INDEX TO VOLUME CXV.

Abbot, S. L. Urethran in chorea, 109; acute rheumatic carditis treated with salicylate of sodium, 326, 328.

Abbott, S. W. Wolpert's air-tester, 131.

Abdominal Surgery. Abdominal cellulitis, Mead, J. A., 199; laparotomy for gun-shot wounds of the intestines, Bull, W. T., 266; a case of abdominal section for chronic suppurative peritonitis, Reeve, J. C., 229; discussion on shot wounds of the intestines, Tremaine, W., 527; what are the diagnostic signs of the involvement of the intestines in shot wounds of the abdomen? Bryant, J. D., 528; what should be the first measures of treatment in shot wounds of the abdomen involving the intestines? Moore, E. M., Jr., 528; under what circumstances and how soon after the injury should laparotomy be resorted to in cases of shot wounds of the intestines, and when is the operation contra-indicated? Bull, W. T., 528; what are the essential features of the technique of laparotomy, including the management of the wounded intestine? Hamilton, J. B., 529; what are the best methods of after-treatment in cases of shot wounds requiring laparotomy and suture of the intestines? Nancrede, 529; laparotomy as a diagnostic resource, Thomas, T. G., 540; a case of gastrotomy: digital exploration of œsophagus and removal of a plate of teeth: recovery, Richardson, M. H., 567, 579.

Adams, I. H. Typhoid fever, 17.

Adams, J. F. A. A case of pneumothorax, 397.

Adams, Z. B. An epidemic of malaria in Eastern Massachusetts, 173, 197.

Age. The reparative power of the aged, 191.

Air-tester. Wolpert's air-tester, Abbot, S. W., 131.

Allen, C. A. Medical common-sense, 16.

Althaus, J. Some phases of cerebral syphilis, 378; on tetany and tetanilla, 389, 417; some points in the pathology and treatment of paraplegia dependent on Pott's disease, 405.

Amenorrhœa. The use of permanganate of potash in amenorrhœa, Lyman, G. H., 61.

Amidon, R. W. A case of hæmatoma of the pancreas: death in three days, 594.

Anatomy. Bicuspid condition of the semi-lunar valves, and its relation to aortic valve disease, Osler, W., 32; recent progress in anatomy, Dwight, T., 265; exhibition of the mediseeted alinjected head of a murderer, Wilder, B. G., 210.

Andrews, J. A. Effects of the electric light upon the eye, 139; the frequent instillation of a two per cent. solution of nitrate of silver in purulent ophthalmia, 187.

Aneurism. Rupture of an aneurism of the thoracic aorta, Read, I. B., 502.

Anidrosis. Congenital anidrosis, Stedman, C. E., 61.

Appendix Vermiformis. Perforating inflammation of the vermiform appendix, with special reference to its early diagnosis and treatment, Fitz, R. H., 13.

Arsenic. Pseudo-tabes from arsenical poisoning, Dana, C. L., 187.

Athetosis, with remarks on its pathology, Hammond, G. M., 407.

Atkinson, I. E. Rubella or rötheln, 237; scarlet fever and scarlatinous eruptions following injuries and operations, 283.

Aubert. A danger from public baths, 266.

Auto-Intoxications, 433.

Ayer, J. B. Whooping-cough at the age of fifty-one: treatment by cresolene, 377; a case of chronic intestinal nephritis, 525; vaccination complicated by a trivial wound, 623.

Bacon, G. A paper on two cases of ear disease due to traumatism, 89.

Bacteria. Demonstration of bacterial cultures from a case of mycotic endocarditis in man, Bruen, E. T., 12; report on bacteriology, Ernst, H. C., 424.

Baelz, E. The physiology of the eye obliquity of the Japanese, 414.

Baker, W. H. Electrolysis in gynæcological surgery, 353; a new portable case for gynæcological instruments, 549.

Bald and toothless future, 415.

Barker, F. The influence of mental impressions on the fœtus, 331.

Baths. The danger of syncope in hot baths, 241.

Beach, H. H. A. Stone in the bladder: lithotomy, 452; stone in the bladder: litholapaxy, 452; tumor of the breast, 452.

Beri-Beri in Brazil, Lane, H. M., 293.

Beevor, C. E. and Horsley, V. Scientific advance in the treatment of tumors of the brain, 69.

Bibliography. American Gynæcological Society Transactions, 1885, 40; Baker, E. C., a guide to the examination of the nose, 381; Blandford, G. F., insanity and its treatment, 530; Buzzard, T., on some forms of paralysis from peripheral neuritis, of gouty, diphtheritic or other origin, 213; California. Ninth biennial report of the state board of health, 553; Dobell, H., on asthma; its nature and treatment, 41; Dujardin-Beaumetz, diseases of the stomach and intestines, 212; Esat, E., the private treatment of the insane as single patients, 553; Féré, C., traité élémentarie d'anatomie médicale on système nerveux, 142; Fothergill, J. M., a manual of dietetics, 213; Gowers, W. R., diagnosis of diseases of the brain and of the spinal cord, 381; Granger, W. D., how to care for the insane, 407; Hammond, W. A., a treatise on diseases of the nervous system, 382; Harvard University, publications of Harvard University and its officers, 1880-1885, 92; Heath, C., dictionary of practical surgery by various British hospital surgeons, 381; Hill, B., the students' manual of venereal diseases, 65; Index catalogue, volume seven, 288; Insane, handbook for the instruction of attendants on the insane, 407; Kircher, J., puerperal convalescence and the diseases of the puerperal period, 456; Lauder-Brunton, T., disorders of digestion; their consequences and treatment, 212; Landis, H. G., the management of labor and the lying-in period: a guide for the young practitioner, 214; Loring, E. G., text-book of ophthalmoscopy, 64; Lydston, G. F., lectures on syphilis, 65; Maclajan, T. J., rheumatism; its nature, its pathology and its successful treatment, 381; Maryland, sixth biennial report of the state board of health, 580; Massachusetts sixth health supplement, 408; Massachusetts registration report, forty-fourth, 382; Morrow, P. A., venereal memoranda, 65; Murrell, W., massage as a mode of treatment, 606; Nail, S., aid to obstetrics, 142; Obstetrical Society of London, Transactions, 1885, 17; Owen, E., the surgical diseases of children, 41; Parker, W. N., elements of the comparative anatomy of the vertebrates, 480; Pennsylvania, first annual report of the state board of health and vital statistics, 553; Phillips, C. D., materia medica and therapeutics, 213; Piffard, H. G., cutaneous memoranda, 65; Roberts, W., lectures on dietetics and dyspepsia, delivered at the Owens College School of Medicine, 212; Sharkey, S. J., spasm in chronic nerve disease, 480; Sutton, J. B., an introduction to general pathology, 504; Trevis, F., a manual of surgery, 285; Warren, J. C., on the healing of arteries after ligature in man and animals, 606.

Bidwell, W. D. Toxic effect from permanganate of potassium, 147; placenta prævia partialis, 376; regulation of the practice of medicine, 558.

Bigelow, J. S. Fractures of the lower end of the humerus, 588.

Biliousness, 116.

Billings, J. S. Medicine in the United States and its relations to co-operative investigation, 121; scientific men and their duties, 561, 585.

Biography. Anderson, J., 361: Bennett, J. I., 292; Bert, P., 485; Brown, F. D., 488; Burke, J., 265; Cleary, T. F., 508; Codman, W. W., 632; Curly, A. H., 244; Dudley, W. H., 361; Durgin, F. A., 464; Edes, R. T., 290; Emerson, J. S., 316; Fisk, S. M., 484; Gamgee, J. S. 361, 364; Gray, J. P., 582; Hamilton, F. H., 170, 196, 338, 429; Hammond, J. S., 536; Hoadley, J. C., 416; Homans, C. D., 268, 292, 385, 460; Holmes, O. W., 217; Hill, H. H., 76; Jackson, W. W., 289; McBride, T. A., 236; Milner, J. F., 460; Moxon, 145; Parks, L., 512, 533; Purdy, B. S., 93; Scully, F. P., 488; Seavey, C., 148; Slack, H., 582; Wakefield, A. T., 416, 437; Wakley, J. G., 288; White, L. H., 312; Woodbury, F. C., 560; Yates, E. S., 120.

Bishop, P. E. A method of treating placenta prævia, some points of which are not to be found in the standard notes on midwifery, 225.

Bishop, W. I. Mind-reading and muscle-reading, 532.

Blache. Dilatation of the stomach in children, 290.

Black-list. A medical black-list, Dixwell, J., 511.

Blackwood. An unusual case of extra-uterine pregnancy, 46.

Blaisdell, F. Report on obstetrics, 15.

Blake, J. G. Albuminuric retinitis, 49, 60.

Blind. The offspring of the blind, Snell, S., 218.

Blodgett, A. N. Dislocation of the ribs, 486.

Boardman, W. E. The management of cases of rigidity of the os uteri in labor, 149; two cases of labor complicated with fibroid tumors, with remarks, 591, 594.

Bowditch, H. I. Lithograph of Vesalius: Holzeming's pharmacopœia: painting by Watteau, 29.

Bradbury, O. N. Severed digits, 583.

Bradford, E. H. The treatment of lateral curvature, 221.

Bradford, E. H. and Lovett, R. W. Report on progress in orthopedic surgery, 373, 398.

Brain. Brain surgery again, 530.

Breast. Tumor of the breast, Beach, H. H. A., 452; axillary lymphangitis with lymphorrhagia? or supernumerary mamma with lacteal secretion, Johnson, A. H., 547.

Brooklyn Bridge. The successful leap from Brooklyn Bridge, 92.

Bronson, E. B. Erythanthema syphiliticum, 236.

Brown, J. F. Theory and practice of medicine, 16.

Bruen, E. T. Notes on some cases of diaphragmatic pleurisy, 1; demonstration of bacterial cultures from a case of mycotic endocarditis in man and of specimens showing the experimental production of the disease in rabbits, 12.

Brune, T. B. A reducing substance in urine resembling glucose, 621.

Bryant, J. D. What are the diagnostic signs of the involvement of the intestines in shot wounds of the abdomen? 528.

Buck, A. H. Painless and only slightly painful ulceration of the membrana tympani probably of a tubercular nature, 86; certain technical details relating to operations on the mastoid process, 87.

Buckingham, E. M. Possible air-embolism after labor, with recovery, 282.
Buckley, J. M. Faith healing and kindred phenomena, 311.
Bull, C. S. An analysis of one hundred cases of exudative retinitis occurring in the course of Bright's disease, 90.
Bull, W. T. Laparotomy for gunshot wounds of intestines, 266; under what circumstances and how soon after the injury should laparotomy be resorted to in cases of shot wounds of the intestines, and when is the operation contra-indicated? 528.
Burnett, C. H. Two cases of chronic purulent inflammation of the attic of the tympanum with perforation of the membrana flaccida treated with peroxide of hydrogen, 88.
Burrell, H. L., and Cushing, H. W. Report on progress in surgery, 177, 227.
Byrne, J. The treatment of procidentia uteri by galvano-cautery, 351.
Bystroff, N. J. Headache in school children, 70.
Cabot, A. T. Care of supra-pubic lithotomy, 455; notes on the treatment of stone in the bladder, 518, 526, 544.
Calculi: their alleged "spontaneous" fracture, 558.
Calculus. Renal calculus, its diagnosis and treatment, Tyson, J., 305; notes on the treatment of stone in the bladder, Cabot, A. T., 518, 526, 544; spontaneous fracture of stone in the bladder, Watson, F. S., 524, 525.
Canfield, H. Health resorts at the South, with remarks on the general subject of climatology, 622.
Carpenter, A. Sewage farming in England, 21.
Carroll, A. L. Lepto-meningitis infantum, 428.
Cellulitis, abdominal, Mead, J. A., 199.
Cerebral Localizations, 603.
Chadwick, J. R. Intestinal resection for malignant stricture of the large intestine, 84; a case of extra-uterine fœtation with presentation of the specimen, 159; the blue discoloration of the vaginal entrance as a diagnostic sign of pregnancy, 355.
Channing, W. Report of a case of epilepsy of forty-five years' duration, with autopsy, 4.
Chapin, C. V. Disinfection and disinfectants, 623.
Charity. Abuse of medical charity: a remedy applied in 3,000 cases of out-door patients: results, Doggett, F. F., 105, 132.
Charleston. The medical college and the Roper Hospital at Charleston, S. C., 314.
Cheever, D. W. A case of chronic obstruction from congenital malformation of the bowels: tentative operation: death, 84; exostosis of facial bones, 596.
Cheltsoff. The effect of bitters on digestion, 21.
Chemistry. Report on medical chemistry, Hills, W. B., 81.
Children. Lowell Island Sanatorium for children, 68; headache in school children, 68; dilatation of the stomach in children, Bache, 290; the etiology and treatment of summer diarrhœa of infants, Haven, H. C., 180; urinary incontinence of children treated by anodynes per rectum, Williams, E. T., 157; cases in the service of Dr. A. T. Cabot, 298; cerebral infantile paralysis, 310; lepto-meningitis infantum, Carroll, A. L., 428; report on diseases of children, Rotch, T. M., 471.
China. Medical Education in China, 19.
Chinese Medicine, 242.
Chloroform. Death from chloroform, 146.
Cholera. The Pope's Cholera Hospital in Rome, 414.
Chorea. Urethane in chorea, Abbot, S. L., 109; the treatment of chorea by cimicifuga, 458; chorea cured by gymnastic exercises during hypnotism, Pari, R., 484.
Chromium. A not well-recognized source of domestic poisoning, with cases, Harrington, C., 135.
Circulatory System. Demonstration of bacterial cultures from a case of mycotic endocarditis in man, Bruen, E. T., 12; the character of inorganic cardiac murmurs, Sawyer, J., 22; a case of "ulcerative endocarditis," Wolcott, G., 25, 30; bicuspid condition of the semi-lunar valves, and its relations to aortic valve disease, Osler, W., 32; report on progress in thoracic disease, Shattuck, F. C., 135; the relations of the inferior thyroid artery and the recurrent laryngeal nerve, Dwight, T., 173; ulcerative endocarditis, Janeway, E. G., 233; possible air-embolism after labor, with recovery, Buckingham, E. M., 282; acute rheumatic carditis treated with salicylate of sodium, Abbot, S. L., 326, 328; pancreatic hæmorrhage and sudden death, Draper, F. W., 350; recent methods of treating hæmorrhoids, 457; two cases of malignant or ulcerative endocarditis, Musser, J. H., 489; the movements of the heart and intestines illustrated by photography, Thompson, W. G., 502; the discovery of the circulation of the blood and its consequences, 505; rupture of an aneurism of the thoracic aorta, Head, I. B., 573; a case of malignant endocarditis, Shattuck, F. C., 574, 577; a case of hæmatoma of the pancreas: death in three days, Amidon, R. W., 594.
Clark, G. A. The medico-legal aspects of suicide in life insurance, 337.
Clinician *versus* patient, 357.
Climate. Health resorts at the South, with remarks on the general subject of climatology, Canfield, H., 622.
Coggin, D. Carded *vs.* absorbent cotton, 510.
Collective Investigation. Committee for collective investigation, International Congress, 607.
Color Blindness. The medico-legal cases, Jeffries, B. J., 137; color blindness among applicants for the navy, Jeffries, B. J., 558.
Co-operative Investigation. Medicine in the United States and its relations to co-operative investigation, Billings, J. S., 121; medicine in the United States and co-operative investigation, 143.
Copeland, W. P. An anodyne for use in vesical irritation, 509.
Corea. Syphilis in Corea, 169.
Corning, J. L. Spinal irritation, its symptoms, pathology and treatment, 541.
Cotton. Carded *vs.* absorbent cotton, Coggin, D., 510.
Councilman, W. T. Certain elements in the blood of malarial fever, 12.
Crosby, G. A. The coming physician, 15.
Currier, D. M. School hygiene, 15.
Cushing, E. W. Fibroid tumor, 209; cases of perforation of the appendix coeci of intestinal obstruction, 575, 578; ovarian tumors, 595.
Cushing, H. W. Phthisis: tubercular synovitis and caries of the wrist: excision with recovery from local condition, 598.
Cutaneous System. Erythema syphiliticum, Bronson, E. B., 236; rubella or rötheln, Atkinson, I. E., 237; report of a case of lymphadenoma (mycosis fungoide) and autopsy, Fox, G. H., 237; a note relative to the bullous eruptions occurring after the ingestion of iodine compounds, Hyde, J. N., 237; precocious gummata, Taylor, R. W., 238; clinical observations regarding the value of resorcin, ichthyol and lanolin in cutaneous diseases, Stelwagon, H. W., 260; trophoneurosis of the skin caused by injury of the median nerve, Tilden, G. H., 260; native plants injurious to the skin, White, J. C., 261; chondroma of the upper lip, Robinson, A. R., 261; keratosis follicularis, associated with fissuring of the tongue and leukoplakia buccalis, Morrow, P. A., 261; a clinical study of scleroderma, Graham, J. E., 261; carcinoma cutis, Denslow Le, G. N., 262; clinical notes on scabies, Greenough, F. B., 269; scarlet fever and scarlatinous eruption following injuries and operations, Atkinson, I. E., 283; remarks and queries on and as to the relative frequency of moles and their pathological changes on the head and face, Sherwell, S., 284; notes of a case of exfoliative dermatitis (pityriasis rubra?) with bullous lesions, Hardaway, W. A., 284; a case of probable tuberculosis of the skin, Tilden, G. H., 285; a few additional notes on psoriasis, Greenough, F. B., 322; report on progress of dermatology, Tilden, G. H., 400; scarlatina *sine* exanthema, 414; on the exact measurement of the electric current and other practical points in the destruction of hair by electrolysis, Prince, M., 420.
Cutler, E. G. Iodoform poisoning, 73, 101, 110.
Dana, C. L. Some certainties in the therapeutics of epilepsy, 22; pseudo-tabes from arsenical poisoning, 187.
Davenport, B. F. Vanilla poisoning, 110; report of progress relating to food and drugs, 546.
Davenport, F. H. Report of progress in gynæcology, 59; physical and chemical qualities of ordinary cow's milk, 180.
Davis, H. G. Intra-capsular fracture, 314; a cure for neuralgia, 486.
Dead. Toilers among the dead, 146.
Debove. Hysterical apoplexy, 461.
Delafield, F. Pulmonary emphysema, 474.
DeLoffre, A. A. More severed digits, 607.
Demons. Resection of lung and removal of a kidney, 413.
Dennett, W. S. A new test-type, 113.
Dennis, F. S. Some points of special interest in the treatment of compound fractures, including a report of over five hundred consecutive cases, 430.
Denslow, Le G. N. Carcinoma cutis, 262.
Derby, H. The possible retardation of retinitis pigmentosa in the young, 113.
Diabetes. On diet in diabetes, Dujardin-Beaumetz, 465.
Diet-tables for, 604.
Digestive System. Perforating inflammation of the vermiform appendix, with special reference to its early diagnosis and treatment, Fitz, R. H., 113; modern views as to functions of the liver, 18, 42; the effect of bitters on digestion, Cheltsoff, 21; foreign bodies in the alimentary canal, Conley, J. W. S., 36; a case of stricture of the ileum: laparotomy, Gay, G. W., 77, 84; operations for the cure of intestinal obstruction, Marcy, H. O., 79, 84; closure of artificial anus by intestinal suture, Porter, C. B., 80, 84; a case of chronic obstruction from congenital malformation of the bowels: tentative operation: death, Cheever, D. W., 84; intestinal resection for malignant stricture of the large intestine, Chadwick, J. R., 84; biliousness, 115; the etiology and treatment of summer diarrhœa of children, Haven, H. C., 180; laparotomy for gunshot wounds of the intestines, Bull, W. T., 266; dilatation of the stomach in children, 290; diaphragmatic hernia, Farraresi, 336; pancreatic hæmorrhage and sudden death, Draper, F. W., 350; follicular tonsillitis, Langmaid, S. W., 455; recent methods of treating hæmorrhoids, 457; perityphlitic abscess discharging spontaneously at the umbilicus, Parker, W. T., 485; the movements of the heart and intestines illustrated by photography, Thompson, W. G., 502; two cases of intestinal obstruction, Wylie, W. G., 503; a simple and ready method of inflating the intestine, Hunt, J., 510; discussion on shot wounds of the intestines, Tremaine, W., 527; what are the diagnostic signs of the involvement of the intestines in shot wounds of the abdomen? Bryant, J. D., 528; what should be the first measures of treatment in shot wounds of the abdomen involving the intestines, Moore, E. W. Jr., 528; under what circumstances and how soon after the injury should laparotomy be resorted to in cases of shot wounds of the intestines, and when is the operation contra-indicated? Bull, W. T., 528; what are the essential features of the technique of laparotomy, including the management of the wounded intestine? Hamilton, J. B., 529; what are the best methods of after-treatment in cases of shot wounds requiring laparotomy and suture of the intestines? Nancrede, 529; the cause of circular gastric ulcer, Silbermann, 534; blowing up the colon or the operator, 535; perforation of the intestine in a case of typhoid fever, Janeway, E. G., 532; a case of gastrotomy: digital exploration of œsophagus and removal of plate of teeth: recovery, Richardson, M. H., 567, 579; cases of perforation of the appendix cœci and of intestinal obstruction, Cushing, E. W., 575, 578; a case of hæmatoma of the pancreas: death in three days, Amidon, R. W., 594; a case of intestinal obstruction in an infant caused by the ingestion of wood, White, W. R., 622.
Diphtheria. Communications from the diphtheria wards of the Charité, Henoch, 21; cases of tracheotomy in diphtheritic croup, Tupper, A. M., 53; a case of puerperal diphtheria, Forster, E. J., 351.
Disinfection. Disinfection and disinfectants, Chapin, C. V., 623.
Dislocations. Backward dislocation of the fingers upon the metacarpus, Otis, E. O., 202, 207; unique case of dislocation of the ribs, Fifield, W. C. B., 453; dislocation of the ribs, Blodgett, A. N., 486; outward dislocation of the patella, Gay, G. W., 502.
Dispensary. Annual report of the Boston Dispensary, 385.
Dixwell, J. A medical black-list, 511.
Doctor as patient, 91.
Doe, O. W. A case of Paris-green poisoning, 301.
Doggett, F. F. Abuse of medical charity: a remedy applied in 3,000 cases of out-door patients: results, 105, 132.
Draper, F. W. Pancreatic hæmorrhage and sudden death, 393; extraordinary cardiac excitement before a first menstruation, 547.

Drilling. Effects of military drill on boys, Sargent, D. A., 245; military drill and gymnastic training in physical culture, Hartwell, E. M., 249; discussion on military drilling, 258.
Driver, S. W. Obstetric gleanings: or expedients and mistakes, 208.
Dujardin-Beaumetz. On complete aliments and on the milk diet, 97; on diet in diabetes, 465; on diet in albuminuria, 513.
"Dunbar" case, Paddock, F. K., 49; the Dunbar case: was it a murder or was it a suicide? Fish, D. B. N., 272.
Dwight, T. The relations of the inferior thyroid artery and the recurrent laryngeal nerve, 173; recent progress in anatomy, 205.
Ear. Recent progress in otology, Gray, J. Orne, 9; acute and chronic purulent inflammation of the middle ear tract and their complications, Sexton, S., 85; a new operation for the radical cure of chronic purulent inflammation of the middle ear tract, Sexton, S., 85; painless and only slightly painful ulceration of the membrana tympani, probably of a peculiar nature, Buck, A. H., 86; certain technical details relating to operations on the mastoid process, Buck, A. H., 87; fatal termination of a case of sclerosing mastoiditis after chiseling of the bone, Knapp, H., 88; a case of abscess of the mastoid cells where the chief indication for operation was elevation of temperature, Pomeroy, O. D., 88; two cases of chronic purulent inflammation of the attic of the tympanum with perforation of the membrana flaccida treated with peroxide of hydrogen, Burnett, C. H., 89; on the physiology of hearing is there an overlapping of each auditory field the same as in binocular vision, Little, W. S., 88; a paper on two cases of ear disease due to traumatism, Bacon, G., 89; abscess of the brain from suppurative otitis, Van Fleet, F., 431; a new ear-speculum. Spear, E. D., 594.
Edes, R. T. Farewell dinner to Dr. R. T. Edes, 296.
Editorials. Modern views as to functions of the liver, 18, 42; medical education in China, 19; is medicine a progressive science? 43; the diagnosis of infectious diseases, 66; glycogenesis and glycosuria, 66; an island sanatorium for children, 66; the doctor as patient, 91; a list of the publications of Harvard University and its officers with the chief publications of the University, 1869-1885, 92; the successful leap from the Brooklyn Bridge, 92; scarlatina and milk, 115; biliousness, 116; poisoning by iodoform, 118; medicine in the United States and co-operative investigation, 143; leprosy in the Hawaiian Islands, 144; lithæmia, 167; syphilis in Corea, 169; the reparative powers of the aged, 191; functions of the thyroid gland, 192; the Somerville poisoning sensation, 192; the State Board of Health to investigate rags as contagion carriers, 214; the hygiene of hot weather, 214; the heat centre, 215; Dr. Oliver Wendell Holmes, 217; the address of Mr. Erichsen at the British Medical Association, 239; State inspection of milk, 240; physical training of American youth, 262; the physiological effects of fear, 263; the overcharge for patent medicines, 264; recent views on "railway spine," 286; the index catalogue, volume seven, 288; cerebral infantile paralysis, 310; faith healing and kindred phenomena, 311; the poisoning of a family by "rough on rats," 312; the formation of new tissue from aseptic blood clots, 333; a medical view of the temperance question, 333; clinician *versus* patient, 357; cysts of the testicle and epididymis, 358; combined sclerosis, 359; the forty-fourth Massachusetts registration report, 382; tuberculosis of the thyroid gland, 383; perforating inflammation of the vermiform appendix, 409; medical sects and clinical instruction in public hospitals, 411; the serpent man, 412; auto-intoxications, 433; hypnotism as a phase of the mind-cure, 434; death by a druggist's error, 436; Thomsen's disease, 457; recent methods of treating hæmorrhoids, 457; the treatment of chorea by cimicifuga, 458; the two hundred and fiftieth anniversary of Harvard College, 459; medical education in the United States, 481; sandal-wood oil as an anti-hæmorrhagic, 482; the discovery of the circulation of the blood, and its consequences, 505; the surgery of the pancreas, 506; Pasteur's new communication on rabies, 507; brain surgery again, 530; are all venereal patients liars? 531; mind-reading and muscle-reading, 532; researches on snake poison, 554; on the treatment of retro-deviations of the uterus, 555; the gastronomic value of odors, 556; the treatment of fractures of the lower end of the humerus, 602; cerebral localization, 603; diet in fevers, 604; increase of insane and paupers in New York, 605; annus medicus, MDCCCLXXXVI, 625.
Education. Medical education in China, 19; researches on snake poison, 554; the best equipment for medical study, Gerrish, F. H., 609.
Elliot, J. W. Tubo-ovarian cyst; hæmorrhage into the tube: operation, 161; three cases of suppurating ovarian tumor treated by drainage, 441, 452; stone in a female bladder, 452; new aseptic sponges, 502.
Embolism. Possible embolism after labor, with recovery, Buckingham, E. M., 282.
Emmet, T. A. Pelvic inflammation: cellulitis *versus* peritonitis, 368.
Endocarditis. A case of ulcerative endocarditis, Wolcott, G., 25, 30; a case of malignant endocarditis, Shattuck, F. C., 574, 577.
Englemann, G. J. Electricity in gynæcological practice, 352.
Epilepsy. Report of a case of epilepsy of forty-five years' duration, with autopsy, Channing, W., 4; some certainties in the therapeutics of epilepsy, Dana, C. L., 22; loss of weight in epilepsy, Hallager, F., 569.
Ergot after labor, Goodman, J., 330.
Erichsen. The address of Mr. Erichsen at the British Medical Association, 239.
Ernst, H. C. Report on bacteriology, 424.
Expert Testimony as given in the courts at present, Holt, A. F., 493, 515.
Extra-Uterine Fœtation. A case of extra-uterine fœtation, Chadwick, J. R., 159.
Extra-Uterine Pregnancy. A case of extra-uterine pregnancy, Kemp, E. A., 28; extra-uterine fœtation, with illustrative case, Lusk, W. T., 34; an unusual case of extra-uterine pregnancy, Blackwood, 46.
Eye. A clinical report of nine cases of hemianopsia, Seguin, E. C., 33; albuminuric retinitis, Blake, J. G., 49, 60; pyogenic micro-organisms with demonstrations and experiments, Knapp, H., 89; an analysis of one hundred cases of exudative retinitis occurring in the course of Bright's disease, Bull, C. S., 90; recent progress in ophthalmology, Wadsworth, O. F. and Standish, M., 106; thrombosis and peri-vasculitis of the retinal vessels, Harlan, G. C., 112; a new test-type, Dennett, W. S., 113; the possible retardation of retinitis pigmentosa in the young, Derby, H., 113; the equivalence of cylindrical and sphero-cylindrical lenses, Jackson, E., 114; the combination of cylinder lenses, Hay, G., 114; two hundred and sixty-three cases of cataract extraction with particular reference to the after-treatment, Strawbridge, G., 114; cataract extraction without iridectomy, Knapp, H., 137; report of fifty cases of cataract extraction, Webster, D., 137; death of a patient on the fifth day after the extraction of a hard cataract, Noyes, H. D., 137; the medico-legal cases, Jeffries, B. J., 139; effect of the electric light upon the eye, Andrews, J. A., 139; a method of overcoming diplopia when prisms are not fully effective, Little, W. S., 139; two epidemics of molluscum contagiosum, Mittendorf, W. F., 140; melano-sarcoma of the conjunctiva and cornea, Mittendorf, 161; the use of hot water in some of the corneal and conjunctival inflammations, Fryer, B. E., 162; asthenopia and the changes in refraction in adult eyes, Norris, W. F., 162; the amblyopia of squinting eyes, Thobald, S., 184; two cases of severe traumatism of eye with partial dislocation of the crystalline lens, Randall, B. A., 185; Badal's operation: laceration of the infra-trochlear nerve for the relief of glaucoma, etc., with cases, Prout, J. S., 185; advancement of Tenon's capsule in strabismus, Knapp, H., 186; a case of tumor of the left occipital lobe, Gruening, E., 186; new formation in the vitreous of both eyes, Prout, J. S., 186; a case of retinitis albuminurica: induced premature labor, Risley, S. D., 187; the frequent instillation of a two per cent. solution of nitrate of silver in purulent ophthalmia, Andrew, J. A., 187; a hint to oculists from the almond-eyed Asiatic, Simmons, G. C., 338; the physiology of the eye obliquity of the Japanese, Baelz, E., 414; pharyngeal and laryngeal mystagmus, 461; report on progress in ophthalmology, Wadsworth, O. F., and Standish, M., 520; color blindness among applicants for the navy, Jeffries, B. J., 558.
Faith healing and kindred phenomena, 311.
Farraresi. Diaphragmatic hernia, 336.
Fear. The physiological effects of fear, 263.
Fehling. The influence of drugs on nurslings, when administered to their nurses, 242.
Fehling's Solution. Reduction of copper in Fehling's solution with chloral hydrate, Sherwin, O. W., 487.
Felons. How to abort a felon, Kelley, H. S., 386; Williams, E. T., 415; abortive treatment of felons, Fish, D. B. N., 463; abortion of felons, wrinkles, new and old, 485.
Felt, M. H. Fashionable follies, 17.
Fevers. Diet in fevers, 604.
Fifield, W. C. B. Unique case of dislocation of the ribs, 453; spontaneous œdema or ascites treated by prolonged drainage through fine canulæ, 624.
Finck, H. T. The gastronomic value of odors, 556.
Fingers. Cases of reunion of cut-off fingers, Ivanoff, S. D., 509; reunion of severed digits, Galloupe, C. W., 511; severed digits, Bradbury, J. N., 563; more severed digits, DeLoffre, A. A., 607.
Fish, D. B. N. The Dunbar tragedy: was it a murder or was it a suicide? 272, abortive treatment of felons, 463.
Fitz, R. H. Perforating inflammation of the vermiform appendix, with special reference to its early diagnosis and treatment, 13.
Food. On complete aliments and on the milk diet, Dujardin-Beaumetz, 97; scarlatina and milk, 115; operation of the acts relative to the adulteration of food and drugs in Massachusetts, 170; physical and clinical qualities of ordinary cows' milk, Davenport, B. F., 180; State inspection of milk, 240; milk supply of large cities and the improvements in which it is conducted, Pooler, H. A., 426; on diet in albuminuria, Dujardin-Beaumetz, 513; the gastronomic value of odors, 556; diet in fevers, 604.
Formad, H. Cyanotic induration of the kidneys, 33.
Formad, M. F. Intra-cranial hæmorrhage: record and classification of one hundred and forty-three consecutive fatal cases observed in medico-legal practice and in private autopsies in the city of Philadelphia, 302.
Foster, E. J. A new nipple-shield, 61; a case of puerperal diphtheria, 351.
Fox, G. H. Report of a case of lymphadenoma (mycosis fungoide) and autopsy, 237.
Fracture, intracapsular, Davis, H. G., 314.
Fractures. Some points of special interest in the treatment of compound fractures, including a report of over five hundred consecutive cases, Dennis, F. S., 499; fractures of the lower end of the humerus, Bigelow, J. S., 588; compound comminuted fracture of the leg, Hayward, G. G., 597; the treatment of fractures of the lower end of the humerus, 602.
Fraenkel. On the treatment of retro-deviations of the uterus, 555.
French Academy's report *re* liquors and liquor saloons, 218.
Fryer, B. E. The use of hot water in some of the corneal and conjunctival inflammations, 162.
Galloupe, C. W. Reunion of severed digits, 511.
Galvin, G. W. Improved inhaler, 181.
Gastric Ulcer. The cause of circular gastric ulcer, Silbermann, 534.
Gastrotomy. A case of gastrotomy: digital exploration of œsophagus and removal of plate of teeth: recovery, Richardson, M. H., 567, 579.
Gavin, M. F. A case of supra-pubic lithotomy, 446.
Gay, G. W. A case of stricture of the ileum: laparotomy: stricture incised and the incision closed with the cœcum: death on the ninth day: autopsy, 77; impalement of the thigh, 502; outward dislocation of the patella, 502.
General Diseases. Spasm of the glottis in rickets, Whittaker, J. T., 11; certain elements found in the blood of malarial fever, Councilman, W. T., 12; typhoid fever, Adams, I. H., 17; communications from the diphtheria wards of the Charité, Henoch, 21; some certainties in the therapeutics of epilepsy, Dana, C. L., 22; the bacillus of typhoid fever, Sternberg, G. M., 32; the attitude of legal medicine *versus* hydrophobia, Spitzka, E. C., 36; scarlatina and milk, 115; leprosy in the Hawaiian Islands, 144; some affections of the nervous system associated with tuberculosis, Weber, L. G., 166; lithæmia, 167; syphilis in Corea, 169; malaria in Eastern Massachusetts, Adams, Z. B., 173, 197; certain points in the diagnosis of some of the infectious diseases, Janeway, E. G., 230; beri-beri

in Brazil, Lane, H. M., 293; notes on syphilis of the nervous system, Putnam, J. J., 317; acute rheumatic carditis treated with salicylate of sodium, Abbot, S. L., 326; some phases of cerebral syphilis, Althaus, J., 378; tuberculosis of the thyroid gland, 383; on diet in diabetes, Dujardin-Beaumetz, 465; are all venereal patients liars? 531.

Generative System. Peri-uterine inflammation, Polk, W., 31; report of progress in gynæcology, Davenport, F. H., 59; the use of permanganate of potash in amenorrhœa, Lyman, G. H., 61; a discussion of the statistics of ovariotomy, Irish, J. C., 153, 159; tubo-ovarian cyst: hæmorrhage into the tube: operation, Elliot, J. W., 161; fibroid tumor, Cushing, E. W., 209; a danger from public baths, Aubert, 266; reflex nervous phenomena from injuries to the testicle, Loumeau, 290; the division of the cervix backward in some forms of anteflexion of the uterus with dysmenorrhœa and sterility, Wilson, H. P. C., 305; another modification of Emmet's operation, with a case in point, Sutton, B. S., 307; notes on the treatment of recent laceration of the cervix uteri, Wilson, E., 307; pelvic inflammation: cellulitis *versus* peritonitis, Emmet, T. A., 308; report on genito-urinary surgery, Post, A., 324; the treatment of procidentia uteri by galvano-cautery, Bryne, J., 351; electricity in gynæcological practice, Engelmann, G. J., 352; electrolysis in gynæcological surgery, Baker, W. H., 352; supra-vaginal hysterectomy, Sutton, R. S., 353; cysts of the testicle and epididymis, 358; three cases of suppurating ovarian cysts treated by drainage, Elliot, J. W., 441, 452; the male urethra, Newell, O. K., 443; fibro-myoma of the uterus, Homans, J., 501; spermatorrhœa, Richardson, M. H., 525; extraordinary cardiac excitement before a first menstruation, Draper, F. W., 547; on the treatment of retro-deviations of the uterus, 555; ovarian tumors, Cushing, E. W., 595; the treatment of prolapse of the uterus and vagina, especially in the aged, with illustrative cases, Green, C. M., 615, 624.

Gerrish, F. H. The best equipment for medical study, 609.

Gibney, V. P. Pseudo-hypertrophic paralysis, 163.

Glycogenesis. Glycogenesis and glycosuria, 66; Glycogenesis, Liebmann, G., 219, 242; about glycogenesis, reply to Dr. Liebmann, 242.

Goodman, J. Ergot after labor, 330.

Gouley, J. W. S. Foreign bodies in the alimentary canal, 36.

Graham, J. E. A clinical study of scleroderma, 261.

Gray, L. C. Lesion of both temporal lobes, causing almost absolute loss of memory of events, without word deafness, or deafness, 162.

Green, C. M. Report on obstetrics, 26; the treatment of prolapse of the uterus and vagina, especially in the aged, with illustrative cases, 615, 624.

Green, J. Orne. Recent progress in otology, 9.

Greenough, F. B. Clinical notes on scabies, 269; a few additional notes on psoriasis, 322.

Gruening, E. A case of tumor of the left occipital lobe, 186.

Gun-shot Wounds. Discussion on shot wounds of the intestines, Tremaine, W., 527; what are the diagnostic signs of the involvement of the intestines in shot wounds of the abdomen? Bryant, J. D., 528; what should be the first measurers of treatment in shot wounds of the abdomen involving the intestines? Moore, E. M., Jr., 528; under what circumstances and how soon after the injury should laparotomy be resorted to in cases of shot wounds of the intestines, and when is the operation contra-indicated? Bull, W. T., 528; what are the essential features of the technique of laparotomy, including the management of the wounded intestine? Hamilton, J. B., 529; what are the best methods of after-treatment in cases of shot wounds requiring laparotomy and suture of the intestines? Nancrede, 529.

Gynæcology. Report of progress in gynæcology, Davenport, F. H., 58.

Hæmatoma. A case of hæmatoma of the pancreas: death in three days, Amidon, R. W., 594.

Hæmorrhoids. Recent methods of treating hæmorrhoids, 457.

Hallager, F. Loss of weight in epilepsy, 509.

Hamilton, J. B. What are the essential features of the technique of laparotomy, including the management of the wounded intestine? 529.

Military Drill. Effects of military drill on boys, Sargent, D. A., 245, 258; military drill and gymnastic training in physical culture, Hartwell, E. M., 249, 258.
Milk. Physical and chemical qualities of ordinary cow's milk, Davenport, B. F., 180; State inspection of milk, 240.
Milk-supply of large cities and the improper method in which it is conducted, Pooler, H. A., 426.
Mills, C. K. Address, American Neurological Association, 140.
Mind. Homœopathic treatment of moral insanity, 69; moral insanity: a plea for a more exact cerebral pathology, Lloyd, J. H., 211; increase of insane and paupers in New York, 605.
Mind-cure. Hypnotism as a phase of the mind-cure, 434.
Mind-reading. Mind-reading and muscle-reading, 532.
Minot, C. S. The actual as compared with the supposed structure of the placenta, 209.
Minot, F. Extensive phlebitis and pelvic abscess following abortion, 279, 282.
Mitchell, S. W. Researches on snake poison, 554.
Mittendorf, W. F. Two epidemics of molluscum contagiosum, 140.
Mittendorf. Melano-sarcoma of the conjunctiva and cornea, 161.
Monks, G. H. A case of unusual deformity of both hip-joints, 468, 479; on rupture of the tendon of the long head of the biceps brachii muscle, 496, 501.
Moore, E. M., Jr. What should be the first measures of treatment in shot wounds of the abdomen involving the intestines? 528.
Moral Insanity: a plea for a more exact cerebral pathology, Lloyd, J. H., 211.
Morrow, P. A. Keratosis follicularis associated with fissuring of the tongue and leukoplakia buccalis, 261.
Mosler. Salicylate of cocaine in asthma, 193.
Muscles. Thomsen's disease, 457.
Musser. Oleum eucalypti in malarial affections, 385.
Musser, J. H. Two cases of malignant or ulcerative endocarditis, 489.
Nancrede. What are the best methods of after-treatment in cases of shot wounds requiring laparotomy and suture of the intestines? 529.
Nephritis. A case of chronic interstitial nephritis. Ayer, J. B., 525.
Nervous System. Report of a case of epilepsy of forty-five years' duration, with autopsy, Channing, W., 4; tetany, Lyman, H. M., 12; nerve weakness, Holbrook, H. C., 17; a clinical report of nine cases of hemianopsia, Seguin, E. C., 33; scientific advance in the treatment of tumors of the brain, Beevor, C. E., and Horsley, V., 69; headache in school children, 70; urethran in chorea, Abbot, S. L., 109; lesion of both temporal lobes, causing almost absolute loss of memory of events, without word deafness, or deafness, Gray, L. C., 162; pseudo-hypertrophic paralysis, Gibney, V. P., 163; multiple tumors of the cerebrum, probably of specific origin, occurring in an infant, McNutt, S. J., 164; the cause of electrotonus and the normal formula of polar reactions, Massey, G. B., 164; report of the committee on electrical dosage, 165; notes on the brain, Wilder, B. G., 165; some affections of the nervous system associated with tuberculosis, Weber, L. G., 166; lithæmia, 167; the relations of the inferior thyroid artery and the recurrent laryngeal nerve, Dwight, T., 173; pseudo-tabes from arsenical poisoning, Dana, C. L., 187; the treatment of facial spasm, Sinkler, 188; intra-cerebral hæmorrhage in the young, Sachs, 188; auctioneer's cramp, Zenner, 189; exhibition of the medisected alinjected head of a murderer, Wilder, B. G., 210; moral insanity: a plea for a more exact cerebral pathology, Lloyd, J. H., 211; recent progress in diseases of the nervous system, Knapp, P. C., 253; reflex nervous phenomena from injuries to the testicle, Lumean, 290; intracranial hæmorrhage, Formad, H. F., 302; cerebral infantile paralysis, 310; notes on syphilis of the nervous system, Putnam, J. J., 317, 328, 341: tenderness of the spine in health and disease, and the therapeutic effects of blistering over the fourth and fifth dorsal vertebræ, Prince, M., 347; combined sclerosis, 359; operations on nerves, Richardson, M. H., 368, 377; some phases of cerebral syphilis, Althaus, J., 378; on tetany and tetanilla, Althaus, J., 389, 417; some points in the pathology and treatment of paraplegia dependent on Pott's disease, Althaus, J., 405; athetosis with remarks on its pathology, Hammond, G. M., 467; lepto-meningitis infantum, Carroll, A. L., 428; abscess of the brain from suppurative otitis, Van Fleet, F., 431; the treatment of chorea by cimicifuga, 458; hysterical apoplexy, 461; chorea treated by gymnastic exercises during hypnotism, Pari, R., 484; a cure for neuralgia, Davis, H. G., 486; loss of weight in epilepsy, Hallager, F., 509; spinal irritation, its symptoms, pathology and treatment, CornING, J. L., 541; a case of professional neurosis of co-ordination, of unusual origin, Knapp, P. C., 577; cerebral localizations, 603.
Neuralgia. A cure for neuralgia, Davis, H. G., 486.
Newell, O. K. The male urethra, 443, 480.
New York Skin and Cancer Hospital, 558.
Nichols, A. H. Fatal poisoning by chloride of zinc applied to an epithelioma of the lip: with remarks, 443.
Nichols, J. T. G. Induced labor at the eighth month on account of pelvic deformity, 541.
Nipple-shield, Forster, E. J., 61.
Nibison, N. The reunion of severed digits, 386.
Northrup, W. P. Laryngeal diphtheria: intubation and pathological anatomy, 598.
Norris, W. F. Asthenopia and the changes in refraction in adult eyes, 462.
Noyes, H. D. Death of a patient on the fifth day after the extraction of a hard cataract, 137.
Obstetric gleanings: or expedients and mistakes, Driver, S. W., 208.
Odors. The gastronomic value of odors, 556.
Orthopraxy. A contribution to the etiology of Pott's disease, Sayre, L. H., 35; the treatment of lateral curvature. Bradford, E. H., 221; report on progress in orthopædic surgery, Bradford, E. H., and Lovett, R. W., 373, 398.
Osler, W. Bicuspid condition of the semi-lunar valves, and its relation to aortic valve-disease, 32.
Otis, E. O. Backward dislocation of the fingers upon the metacarpus, 202, 207.
Otis, F. N. Bladder evacuator, 501.
Ovariotomy. A discussion of the statistics of ovariotomy, Irish, J. C., 153, 159.
Paddock, J. K. The "Dunbar" case, 49.
Palmer, S. E. A case of puerperal eclampsia, 349.
Pancreas. Pancreatic hæmorrhage and sudden death, Draper, F. W., 393; the surgery of the pancreas, 506.
Paraldehyde. A contra-indication of paraldehyde, Sommer, 241.
Pari, R. Chorea cured by gymnastic exercises during hypnotism, 484.
Paris-green. A case of Paris-green poisoning, Doe, O. W., 301.
Parrish, W. H. The high mortality of the recent cæsarean operations in the United States, with the report of a case, 356.
Pasteur's new communication on rabies, 507.
Patent Medicines. The overcharge for patent medicines, 264; endorsing proprietary medicines, "John Collins, of Podunk," 226.
Pathology. Recent progress in pathology and pathological anatomy, Whitney, W. F., 448, 498.
Physical Training. Effects of military drill on boys, Sargent, D. A., 245; military drill and gymnastic training in physical culture, Hartwell, E. M., 249; discussion on military drill, 258; physical training of American youth, 262.
Physiology. Modern views as to functions of the liver, 18; glycogenesis and glycosuria, 66; on glycogenesis ? ? bmann, G., 219, 242; about glycogenesis: reply to Dr. Liebman ? ?2; the physiological effects of fear, 263.
Placenta. The actual as compared with the supposed structure of the placenta, Minot, C. S., 209.
Placenta Prævia. A method of treating placenta prævia, some points of which are not to be found in the standard works on midwifery, Bishop, P. E., 225; placenta prævia partialis, Bidwell, W. D., 376.
Pleurisy. Notes on some cases of diaphragmatic pleurisy, Bruen, E. T., 1.
Poisons. Iodoroform poisoning, Cutler, E. G., 73, 101, 110, 118; vanilla poisoning, Davenport, B. F., 110; a not well-recognized source of domestic poisoning, with cases, Harrington, C., 135; toxic effect from permanganate of potassium, Bidwell, W. D., 147; poisoning by ice cream, Vaughan, V. C., 218; pseudo-tabes from arsenical poisoning, Dana, C. L., 187; the use and abuse of ergot, 194; overdose of hydrobromate of hyoscin, Webber, S. G., 207; a case of Paris-green poisoning, Doe, O. W., 301; the poisoning of a whole family by "rough on rats," 312; fatal poisoning by chloride of zinc applied to an epithelioma of the lip: with remarks, Nichols, A. H., 343.
Polk, W. Peri-uterine inflammation, 31.
Pomeroy, O. D. A case of abscess of the mastoid cells where the chief indication for operation was elevation of temperature, 88.
Pooler, H. A. The milk-supply of large cities and the improper method in which it is conducted, 426.
Porter, C. B. Closure of artificial anus by intestinal suture, 80, 84.
Post, A. Report on genito-urinary surgery, 324.
Pott's Disease. A contribution to the etiology of Pott's disease, Sayre, L. H., 35.
Practice of Medicine. The coming physician, Crosby, G. A., 15; theory and practice of medicine, Brown, J. F., 16; regulation of the practice of medicine, Bidwell, W. D., 558.
Pregnancy, affections connected with. Report on obstetrics,

Blaisdell, F., 15; **Green, C. M.**, 26; a case of extra-uterine pregnancy, **Kemp, E. A.**, 28; extra-uterine fœtation, with illustrative case, **Lusk, W. T.**, 34; an unusual case of extra-uterine pregnancy, **Blackwood**, 46; salt infusion in the treatment of hæmorrhage, **Harrington, F. B.**, 61; congenital anidrosis, **Stedman, C. E.**, 61; the future influence of surgery and surgical resources upon obstetrics, **Lee, C. C.**, 62; the management of cases of rigidity of the os uteri in labor, **Boardman, W. E.**, 149; a case of extra-uterine fœtation, **Chadwick, J. R.**, 159; a case of retinitis albuminurica: induced premature labor, **Risley, S. D.**, 187; obstetric gleanings or expedients and mistakes, **Driver, S. W.**, 208; the actual as compared with the supposed structure of the placenta, **Minot, C. S.**, 209; a method of treating placenta prævia, some points of which are not to be found in the standard works of midwifery, **Bishop, P. E.**, 225; extensive phlebitis and pelvic abscess following abortion, **Minot, F.**, 279, 282; possible embolism after labor, with recovery, **Buckingham, E. M.**, 282; ergot after labor, **Goodman, J.**, 330; a case of puerperal eclampsia, **Palmer, S. E.**, 349; a case of puerperal diphtheria, **Forster, E. J.**, 321; the blue discoloration of the vaginal entrance as a diagnostic sign of pregnancy, **Chadwick, J. R.**, 335; the high mortality of the recent cæsarean operation in the United States, with the report of a case, **Parrish, W. H.**, 356; placenta prævia partialis, **Bidwell, W. D.**, 376; two cases of obstetric interest, **Hosmer, A.**, 402, 404; induced labor at the eighth month on account of pelvic deformity, **Nichols, J. T. G.**, 548; two cases of labor complicated with fibroid tumors, with remarks, **Boardman, W. E.**, 591, 594.

Prince, M. Tenderness of the spine in health and disease and the therapeutic effects of blistering over the fourth and fifth vertebræ, 347; on the exact measurement of the electric current and other practical points in the destruction of hair by electrolysis with special reference to the use of the absolute galvanometer, 429.

Prizes. The Ernest Krackonizer prize, 502.

Prout, J. S. Badal's operation: laceration of the infra-trochlear nerve for the relief of glaucoma, with cases, 185: new formation in the vitreous of both eyes, 186.

Putnam, J. J. Notes on syphilis of the nervous system, 317, 328, 341.

Rags. Order to customs officers in regard to importation of old rags, 119; the State Board of Health to investigate rags as contagion carriers, 214.

Railway Spine, 286.

Randall, B. A. Two cases of severe traumatism of the eye with partial dislocation of the crystalline lens, 185.

Reamy, T. A. Address before American Gynæcological Association, 331.

Read, I. B. Rupture of an aneurism of the thoracic aorta, 552.

Recent Progress. Otology, **Green, J. Orne**, 9; obstetrics, **Green, C. M.**, 26; gynæcology, **Davenport, F. H.**, 59; medical chemistry, **Hills, W. B.**, 81; ophthalmology, **Wadsworth, O. F.** and **Standish, M.**, 106; thoracic disease, 155; surgery, **Burrell, H. L.** and **Cushing, H. W.**, 177, 227; anatomy, **Dwight, T.**, 205; nervous system, **Knapp, P. C.**, 253; therapeutics, **Williams, F. H.**, 276, 296; genito-urinary surgery, **Post, A.**, 324; orthopædic surgery, **Bradford, E. H.**, and **Lovell, R. W.**, 373, 398; dermatology, **Thorn, C. B.**, 406; bacteriology, **Ernst, H. C.**, 424; pathology and pathological anatomy, **Whitney, W. F.**, 448, 498; children, **Rotch, T. M.**, 471; report on progress in ophthalmology, **Wadsworth, O. F.** and **Standish, M.**, 520; report of progress relating to food and drugs, **Davenport, B. F.**, 546.

Reeve, J. C. A case of abdominal section for chronic suppurative peritonitis, 229.

Registration. Forty-fourth Massachusetts registration report, 382.

Respiratory System. Notes on some cases of diaphragmatic paralysis, **Bruce, E. T.**, 1; spasm of the glottis in rickets, **Whittaker, J. T.**, 11; an improved method of measuring the chest, **Wilkins**, 17; report on progress in thoracic disease, **Shattuck, F. C.**, 155; salicylate of cocaine in asthma, **Mosler**, 193; whooping-cough at the age of fifty-one: treatment by cresolene, **Ayer, J. B.**, 377; a case of pneumothorax, **Adams, J. F. A.**, 397; resection of lung and removal of a kidney, **Demons**, 413; follicular tonsillitis, **Langmaid, S. W.**, 455; pulmonary emphysema, **Delafield, F.**, 474; phthisis: tubercular synovitis and caries of the wrist: excision with recovery from local condition, **Cushing, H. W.**, 598; phthisical lung, injected with carbolized iodine, **White, J. B.**, 598; laryngeal diphtheria: intubation and pathological anatomy, **Northrup, W. P.**, 598.

Richardson, M. H. Operations on nerves, 368, 377; spermatorrhœa, 525; a case of gastrotomy: digital exploration of œsophagus and removal of plate of teeth: recovery, 567, 579.

Rickets. Spasm of the glottis in rickets, **Whittaker, J. T.**, 11.

Risley, S. D. A case of retinitis albuminurica: induced premature labor, 187.

Robinson, A. R. Chondroma of the upper lip, 261.

Rotch, T. M. Report on diseases of children, 471.

Rome. On the hygienic laws and sanitary conditions of ancient Rome, **Lanciani, R.**, 537, 565.

Saccharine. Fahlberg's saccharine, **Leale, C. A.**, 553.

Sachs. Intracerebral hæmorrhage in the young, 188.

Salt Solution. Subcutaneous injection of salt solution, **Tuttle, W. H.**, 362; salt infusion in the treatment of hæmorrhage, **Harrington, F. B.**, 61.

Sandal-wood oil as an anti-blenorrhagic, 482.

Sargent, D. A. The effects of military drill on boys, 245, 258.

Sawyer, J. The character of inorganic cardiac murmurs, 22.

Sayre, L. H. A contribution to the etiology of Pott's disease, 35.

Scabies. Clinical notes on scabies, **Greenough, F. B.**, 269.

Scarlatina. Scarlatina and milk, 115; scarlatina *sine* exanthema, 414.

School Hygiene. **Currier, D. M.**, 15.

Scientific Men and their duties, **Billings, J. S.**, 561, 585.

Sedgwick, W. F. The purification of drinking-water by filtration, 470, 476.

Seguin, E. C. A clinical report of nine cases of hemianopsia, 32.

Serpent-man, 412.

Sewage farming in England, **Carpenter, A.**, 21.

Sexton, S. Acute and chronic purulent inflammation of the middle ear tract and their complications, 85; a new operation for the radical cure of chronic purulent inflammation of the middle ear tract, 85.

Shattuck, F. C. Report on progress in thoracic disease, 155; a case of malignant endocarditis, 574, 577.

Shattuck, G. B. Report on water-supply, 181.

Sherwell, S. Remarks and queries on and as to the relative frequency of moles and their pathological changes on the head and face, 284.

Sherwin, O. W. Reduction of copper in Fehling's solution with chloral hydrate, 487.

Silbermann. The cause of circular gastric ulcer, 534.

Simmons, G. C. A hint to oculists from the almond-eyed Asiatic, 338.

Simpson, J. Y. The functions of the thyroid gland, 618.

Sinkler. The treatment of facial spasm, 188.

Snake-poison. Researches on snake poison, 554.

Snell, S. The offspring of the blind, 218.

Societies. American Academy of Medicine, 432; American Dermatological Association, 234, 259, 283; American Gynæcological Society, 305, 329, 351; American Neurological Association, 140, 162, 187, 210; American Ophthalmological Society, 89, 112, 137, 161, 184; American Otological Society, 85; American Public Health Association, 362; Association of American Physicians, 11, 31; Boston Society for Medical Improvement, 109, 328, 377, 452, 525, 623; Boston Society for Medical Observation, 207, 351, 454; British Medical Association, 239; Congress of American Physicians and Surgeons, 313; Essex North District Medical Society, 404; Greece Royal Medical Society, 536; International Medical Congress, 119; Massachusetts Medical Society, 29, 476; Massachusetts Medical Benevolent Society, 456; Massachusetts Medico-Legal Society, 426; New Hampshire Medical Society, 14; New York Academy of Medicine, 62, 378, 405, 474, 502, 598; New York County Medical Association, 34, 230, 429, 549; New York State Medical Association, Fifth District Branch, 428, 527; Obstetrical Society of Boston, 60, 282, 404, 547; Philadelphia Pathological Society, 362; Rhode Island Medical Society, 622; Suffolk District Medical Society, 84, 159, 180, 208, 258, 479, 501, 577, 579, 594, 596.

Somerville poisoning sensation, 192.

Somnos. A contra-indication of paraldehyde, 241.

Souther, W. P. The reuniting of severed digits, 339.

Spear, E. D. A new ear-speculum, 594.

Spermatorrhœa, Richardson, M. H., 525.

Spinal Irritation, its symptoms, pathology and treatment, **Corning, J. L.**, 541.

Spitzka, E. C. The attitude of legal medicine *versus* hydrophobia, 36.

Sponges. New aseptic sponges, **Elliot, J. W.**, 502.

Stanley, A. A new portable battery and some details of its application, 404.

Stedman, C. E. Congenital anidrosis, 61.

Stelwagon, H. W. Clinical observations regarding the value of resorcin, iethyol, and lanolin in cutaneous diseases, 260.

Sternberg, G. M. The bacillus of typhoid fever, 32.

Strawbridge, G. Two hundred and sixty-three cases of cataract extraction with particular reference to the after-treatment, 114.

Suicide. The medico-legal aspects of suicide in life insurance, **Clark, J. A.**, 337.

Surgery. Report on surgery, **Hammond, C. B.**, 16; recent progress in surgery, **Burrell, H. W.**, and **Cushing, H. W.**, 177, 227; backward dislocation of the fingers upon the metacarpus, **Otis, E. O.**, 202, 207; on rupture of the tendon of the long head of the biceps brachii muscle, **Monks, G. H.**, 496, 501; notes on the treatment of stone in the bladder, **Cabot, A. T.**, 518, 526; brain surgery again, 530; exostosis of facial bones, **Cheever, D. W.**, 596.

Sutcliffe, R. S. Another modification of Emmet's cervix operation, with a case in point, 307.

Sutton, R. S. Supra-vaginal hysterectomy, 355.

Syphilis. Syphilis in Corea, 169; some phases of cerebral syphilis, **Althaus, J.**, 378; Syphilis of the nervous system, **Putnam, J. J.**, 317, 328, 341; are all venereal patients liars? 531.

Taft, R. W. Precocious gummata, 238.

Taylor, W. H. Notes on the Lawton murder, 318.

Tea. The use and abuse of tea, 194.

Temperance. Medical view of the temperance question, 333.

Testicle. Reflex nervous phenomena from injuries to the testicle, **Lumeau**, 296.

Tetany, Lyman, H. M., 12; tetany and tetanilla, **Althaus, J.**, 389, 417.

Theobald, S. The amblyopia of squinting eyes: is it a determining cause or a consequent of the squint? 184.

NOTES ON SOME CASES OF DIAPHRAGMATIC PLEURISY.[1]

BY EDWARD T. BRUEN, M.D.,

Assistant-Professor Physical Diagnosis, University of Pennsylvania, Physician to the Philadelphia Hospital, etc.

It has been my fortune to make a number of post-mortem examinations in which diaphragmatic pleurisy has been found present in marked form. In considering the clinical symptomatology, as studied ante-mortem, the results have yielded very varied evidence as to the practicability of recognizing this disease at the bedside. The object of this paper is to briefly state, from the clinical standpoint, the diagnostic features of diaphragmatic pleurisy. The statements I have to offer I have entitled notes, since they have been based on cases which have passed under my observation, without attempting a review of the interesting historical literature of the disease. It is unquestionable that the positive diagnosis of diaphragmatic pleurisy may only be established at the post-mortem table, since the process is often latent, and frequently possesses few distinctive physical signs.

Diaphragmatic pleurisy, as a primitive disease, is certainly infrequent, when traumatic causes are excluded. It is oftener a complication attendant upon acute inflammatory processes in the adjacent pulmonary lobes, the costo-parietal pleura, or in the liver or peritoneum. Inflammation of the diaphragmatic pleura also occurs in some cases of pyæmic inflammation of the serous membranes.

Under the foregoing conditions, invasion of the diaphragmatic pleura may be characterized by special symptoms, which may entitle one to designate this class of cases as acute inflammation of the diaphragmatic pleura.

Inflammation of this portion of the pleura may also be sub-acute or chronic, but developed in consequence of contiguous sub-acute or chronic inflammatory processes, or malignant growths. In such examples, the process in the diaphragmatic pleura may become specialized by symptoms which should lead the clinician to differentiate the diaphragmatic pleurisy from the associated pathological changes.

My notes upon cases manifesting the acute form of this disease would seem to show that, in such cases, many of the more prominent and differential symptoms may be masked by the greater importance of the primary disease. For example, in a case of croupous pneumonia of the apex of the lung, occurring in the Philadelphia Hospital during my present term of service, in which the process advanced through the lobes of the right lung, finally reaching the lower lobe by the end of the fifteenth day of the illness, diaphragmatic pleurisy was developed. The patient was delirious with typhoid state marked; yet the development of the new complication was characterized by pain over the hypochondriac region, extending over the flank to the inferior dorsal region of the right side, by hiccough, and irritation of the phrenic nerves, as shown by tenderness on pressure along their course. The hiccough was not constant, but was aroused by the passage of food into the stomach, or by its presence in that viscus, or accumulation of gas in the abdominal viscera, and was augmented when the patient, by moving, increased the frequency of respiration. Hiccough was sometimes similarly excited, but was always diminished in frequency or subdued by the use of morphia hypodermically, but was not relieved by the anti-spasmodics which are useful when the diaphragmatic irritability is traceable to the central nervous system.

It is stated that in diaphragmatic pleurisy, the position of the sufferer during a paroxysm of pain and dyspnœa corresponds with that observed under like conditions in emphysematous subjects, that is, inclined forward, so as to lessen the diaphragmatic movement. But in this case, as in most instances of diaphragmatic pleurisy in connection with acute types of disease, the position was not characteristic. The post-mortem confirmed the ante-mortem diagnosis.

The symptoms of diaphragmatic pleurisy associated with peri-hepatitis, or inflammatory processes originating in the peritoneum, are very often obscured and rendered inconspicuous by the conditions associated with these processes. For instance, the enlargement of the liver, or the distension of the intestines with gas, may so sensibly modify the freedom of the diaphragmatic movement that the respiration may be costal, and the immobility of the diaphragm, one of the prominent symptoms of diaphragmatic pleurisy, may not be differentiated, and assigned to its true cause.

The symptom of hiccough may be suppressed by similar conditions, while the posture of a patient suffering from diaphragmatic pleurisy is not usually at all characteristic. Very often, however, the characteristic pain over the situation, elsewhere designated, the added disablement of the respiratory function may be noticeable. Friction fremitus between the liver and edge of the ribs should lead one to suspect diaphragmatic pleurisy.

Concurrently with inflammation of the diaphragmatic pleura, friction râles may be audible along the line of union of the diaphragm with the lung. The râles are probably produced in the bronchial tubes in the lung bordering the diaphragm, and are caused by the hypostatic congestion which ensues upon the want of functional play of the lower zone of the chest. The icteroid tint and clay-colored stools may be associated symptoms in diaphragmatic pleurisy, concurrent with perihepatitis. In most of the cases which I have seen, the right side of the diaphragmatic pleura was invaded.

The termination of acute diaphragmatic pleurisy is intertwined with the associated pathological processes, and the gravity of a case is not necessarily increased if the symptom of hiccough is subordinate. In some apparently primary cases, a favorable issue may occur. In support of the foregoing statements, and as a typical example, let me briefly state the pertinent features of the case of X, a negro thirty-one years of age, who entered the Philadelphia Hospital, March 5. On examination, the diaphragm appeared fixed, the liver pushed below its normal position. The organ was also swollen and enlarged. Pain distributed over the diaphragmatic zone and at points elsewhere mentioned as characteristic. Friction râles were distinctly audible along the line of approximation of the visceral with the diaphragmatic pleura. Dyspnœa was marked, with jerky, enfeebled respiratory murmur, especially over lower lobe of the lung, together with slight dulness on percussion. The cardiac action was rapid. Subsequently, disseminated areas of consolidation appeared

[1] Read at the first annual meeting of the Association of American Physicians, at Washington, June 17, 1886.

through the right lung, from apex to base, apparently due to congestion, since the normal physical signs reappeared within a week. Concurrently, an œdematous boss as large as a silver dollar, occupied the anterior axillary line over the right lobe of the liver; one or two other similar swellings appeared over the right inferior axillary region. These bosses were so soft and fluctuating as to lead me to make an exploratory aspiration of the liver. The needle was introduced three times fruitlessly, so far as finding pus, but without injury to the patient. The areas of œdema seemed to me attributable to sudden interference with the circulation through the diaphragmatic and intercostal lymphatic systems, on account of the suspended functional play of the diaphragm and intercostal muscles upon which the circulation of these lymphatics depends. Similar œdema of the intercostal muscles occurs in certain cases of emphysema. There was no hiccough. This case terminated in complete recovery after the expiration of five weeks.

To show, however, that the acute forms of diaphragmatic pleurisy may progress to a marked degree without (even to expectant attention) the manifestation of diagnostic symptoms, I append a recent post-mortem held June 12th, at the Philadelphia Hospital, on a young colored man, aged nineteen. The lesions of acute miliary tuberculosis were found through the right and left lungs, secondary, on clinical ante-mortem evidence, to costo-parietal pleurisy. The right diaphragmatic pleura was found thickened to an inch by the deposit of lymph covering a dense layer of miliary nodules of tubercle, with comparatively little change in the costal pleura. The abdominal aspect of the diaphragm was also covered with miliary nodules, indicating that the extensive tubercular peritonitis which was formed had probably been developed through transferrence of elements from the pleural process through the diaphragmatic lymphatics, by which there is a connective channel between the pleural and peritoneal lymphatics.

During life the diagnosis of the miliary tuberculosis and of the costo-parietal pleurisy was positively established, but the only symptom which suggested involvement of the diaphragmatic pleura was the numerous friction râles heard along the upper border of the fifth rib and near the margin of the seventh rib in axillary line, and this, although it was known that a considerable amount of fluid was contained in the pleural cavity. The râles were doubtless developed by the friction between the diaphragmatic pleura over the convexity of the liver, and the visceral pleura over the concavity of the lower pulmonary lobe. The lung itself rendered hard and inelastic by the tubercular infiltration, projected in rigid immovable form into the pleural cavity, displacing the effusion around it.

As already indicated in the outset, the sub-acute or chronic forms of diaphragmatic pleurisy, although combined with other lesions, impart certain conspicuous characters to the symptoms, which are less obscured by the intercurrent disease than in many cases of the acute forms of the disease. The following case may be appealed to as reasonably typical: J. G., aged forty-four, admitted to Philadelphia Hospital 8.12.1885. Dates his illness to a cold two years ago, and has had cough ever since. When examined, the usual physical signs revealed fairly marked emphysema, with indurative consolidation of the right apex. It was noted, however, that the liver was displaced downward three inches from the eighth rib in the axillary region, the dulness in the nipple line extended two inches on line with inferior margin of ribs. A localized spot of tenderness was found two and one-half inches from the edge of ribs near a line prolonged from the inner border of the sternum, resembling the *button diaphragmatique*) of De Mussy. Tenderness was felt in the lower intercostal spaces behind, near the spine, and also along the course of the phrenic nerves, near the borders of the sternum, and especially under the lower insertion of the sterno-cleido mastoid muscle. The attitude of the patient was always inclined forward, especially during attacks of pain, which came on paroxysmally several times daily, notably when food was taken. Sometimes exudations of gas occurred during a paroxysm of pain, which seemed to give relief. The most conspicuous feature was fixation of the diaphragm, which occasioned superficial shallow breathing. The respiration was mostly costal and limited to the upper part of the chest. Inspection showed retraction of the hypochondriac and epigastric regions, and also of the interspaces between the lower ribs to a greater degree than could be accounted for by the emphysema. It was held that the diaphragmatic pleurisy had been secondary to costo-parietal pleurisy, the characteristic symptoms separating the diaphragmatic disease from the associated emphysema, being the posture, the fixation of the diaphragm, the areas of tenderness, the paroxysmal pain. The retraction of the epigastic and hypochondriac regions was due to the forward inclination of the person, assumed to lessen the play of the diaphragm, and facilitate superior costal respiration. It was necessary, in this case, to exclude from the clinical picture gastric ulcer, since the tenderness over the epigastrium was very local; circumscribed peritonitis, and gall-stone, (the latter suggested by the icteroid tint which was always more marked after a paroxysm of pain), were also set aside by appropriate methods. The post-mortem in this case confirmed the diagnosis. On both sides the diaphragmatic pleura was thickened and adherent to the pulmonary lobes. The lungs were emphysematous with induration of the right upper lobe. There were adhesions over the axillary region between the costo-parietal and visceral layers of the pleura on the right side. Phrenic nerves apparently normal.

One must be prepared for wide variations in the symptoms of this interesting disease, for the power of adaptation possessed by the system is very great, as we can see illustrated by the long period during which an adherent pericardial sac can be tolerated. Moreover, even deficiency of diaphragmatic structure may occur without marked symptoms. In a case reported to the Philadelphia County Medical Society by the writer, very great thickening to the extent of three inches occurred in the entire pleura of the left lung. Between the first and fourth ribs, near the sternum, the costal cartilages had been bulged outward over the area of thickened pleura. The lungs upon the left side were infiltrated by desquamative pneumonic processes with cavities. The muscular tissue of the diaphragm was entirely absent, as was also the pericardial tissue. These latter changes were doubtless congenital. The liver was folded upon itself, and drawn up into the chest cavity as high as the second rib at its outer portion. The absence of the pericardium permitted the heart to yield to the traction of the pleural adhesions, and the apex was tilted upward and to the

left, so that during life the apex pulsation was felt in the fourth interspace four and one-half inches from the left border of the sternum. The patient dated his symptoms to a period eight years prior to his death. He complained especially of pain in and around the chest, with shortness of breath accompanied with asthmatic attacks. The patient was thirty-two years old at death, consequently as the first twenty-four years of his life had been free from distress, it was reasonable to ascribe the above symptoms to the onset of the pleurisy.[2]

In a case very fully reported by Tyson,[3] the diaphragmatic pleura of the right side was covered with gray granulations, and thickened, as was also the costal surface of the right pleura, and yet none of the so-called diagnostic symptoms of diaphragmatic pleurisy had been recorded. But in a case of intra-thoracic cancer, involving pleura, diaphragm and chest-walls, reported by Pepper,[4] I would call attention to certain symptoms. "Marked pleural effusion on right side, with violent orthopnœa. The physical signs were localized chest pain, absence of respiratory sounds and dulness on the right side. These signs gradually diminished, and in a month the patient was much better. There was return of resonance, diminution in pain, and much improvement in general health. During the whole period of the patient's illness there was marked disturbance of the liver, with heavily coated tongue and torpid bowels. The effusion returned in about two months with the orthopnœa. There then appeared for the first time distinct prominences upon the chest walls, with severe pain. The first prominence appeared over the ninth rib posteriorily four inches from the spine. The second appeared below the sternal end of the right clavicle, the third on the right side in the line of the arm-pit, about the tenth rib. . . . Sleep was disturbed by the intense pain, which was constant, but also increased paroxysmally. The pain was most felt at the points of prominence, but also extended down the nerves of the right arm."

The post-mortem record showed the tumor mass on the posterior surface was very large and extensive, and involved both layers of the pleura and also the superficial layer of lung tissue at a few points. It reached from the third rib down to the diaphragm and was fully an inch thick in some places. The mass low down on the right side was smaller, also involved both layers of the pleura and was continuous with a large growth which involved the whole thickness of the diaphragm. The anterior part of this muscle was chiefly affected: the growth in places was fully one-half to two inches in thickness, and the disease extended across the median line where it was continuous with the mediastinal growth before described. At one spot over the convexity of the liver, there was an extension of cancerous disease to the capsule and superficial layer of the tissue of that organ. There was no pleural effusion, though during life small amounts of fluid had from time to time been withdrawn by aspiration. The tender spots, while directly traceable to the growths, yet occupied the characteristic situations of tenderness indicative of diaphragmatic disease. Again, Dr. Daland of Philadelphia, has related to me the notes of a case occurring in a woman, under his care, who died from cancer of the breast, in whom, on post-mortem, the right lung was found completely adherent to the diaphragm by a union which must have seriously crippled the expansion and contraction of that lobe, and indeed that side, and yet she presented no symptoms of pulmonary embarrassment by which the lesion could have been suspected.

The diagnosis of a disease in which there is often so little that is distinctive, must necessarily be a difficult problem. I have shown by the relation of several post-mortem examinations that this process can exist in advanced form on one side of the diaphragm at least without special symptoms. If the diaphragmatic pleurisy should complicate any form of pulmonary disablement, or pathological process in the liver, or circumscribed peritonitis of the superior part of the abdominal cavity, one may note that the subjective sense of respiratory distress, and the objective symptoms are disproportionate to these conditions, and therefore the possibility of the existence of diaphragmatic pleurisy should be considered.

The more important diagnostic symptoms which, if present, indicate diaphragmatic pleurisy may be ranged in the order of their frequency and importance, as follows: subjective sensation of pain over the zone which borders the diaphragmatic plane, pain on pressure at the *button diaphragmatic* of De Mussy, namely,[5] one or two fingers' breadth from the middle line on a level with the tenth rib, or at the intersection of a line drawn from the osseous part of the tenth rib and one drawn along the border of the sternum. De Mussy explains the greater pain at this point by the greater play of the ribs and consequent friction against the inflammed nerve. Whether the nerve is actually inflammed, or simply irritated, must as yet await investigation by further post-mortem examinations. The pains may be constant, yet also paroxysmal, or evoked by pressure, by increased respiratory motion, by irritation of the diaphragm, by swallowing, or vomiting, or by the pressure of the distended abdominal viscera. Radiating pains around the chest and upper abdominal zone may occur. Fixation of the diaphragm is an equally important symptom, and secondarily, the enforced thoracic character of the respiration is a very striking phenomena. There will usually be feeble, or absent respiratory murmur near the diaphragmatic zone.

Dry or moist friction râles may be audible along the convex surface of the diaphragmatic pleura. The percussion resonance may be dull when there is much exudation, but more commonly I have found it tympanitic, since the partial paresis of the diaphragmatic muscle permits the pressure of the abdominal viscera to raise it somewhat above its usual area. In certain cases the posture of the patient may be bent forwards with retraction of the hypochondriac region and epigastric hollowness, but the dorsal decubitus is very often maintained. The respirations are quickened in acute cases, so that there may be dyspnœa, or orthopnœa, but these symptoms may be almost entirely absent in sub-acute or chronic cases on account of compensatory costal respiration. Cough is a variable symptom, and the same may be said of hiccough; both are very often absent. Finally, in the writer's experience, diaphragmatic pleurisy has been chiefly a thickening with adhesions rather than accompanied by much fluid exudation. Hence the importance of noting the foregoing symptoms since the presence of much fluid exudation would

[2] See Trans. Phila. County Med. Soc., Vol. 5, p. 111.
[3] See Trans. Path. Soc., Phila., Vol. 5, p. 122.
[4] Trans. Path. Soc., Phila., Vol. 7, p. 71.
[5] Arch. Gen. de Med., 1853, vol. 2, p. 274.

be much more obvious, by means of percussion, auscultation and other physical signs.

Aside from any discussion of the differential diagnosis as separating diaphragmatic pleurisy from costo-parietal pleurisy, or processes in the lower pulmonary lobes, or in the pericardium; and aside from a discussion of the differential symptoms separating the disease under discussion from perihepatitis, or circumscribed peritonitis in the upper part of the abdominal cavity, one must consider in certain cases the diagnosis by exclusion of gastric ulcer, and this particularly if the *button diaphragmatique* should be manifest. Multiple ulcers of the stomach may advance without symptoms quite to the period of perforation into the peritoneal cavity, but the pain in certain other cases of this disorder has a wide distribution radiating to the back and along the shoulders. In gastric ulcer the symptoms may be aggravated by the ingestion of food, and vomiting may follow. In diaphragmatic pleurisy the ingestion of food may cause pain by the distension of the stomach, which will induce pressure against the diaphragm; with this there may be coughing, and even vomiting. The differential diagnosis may only be settled after a rigid analysis of the etiological relations of the array of symptoms. In some cases the paroxysmal character of the pain, the icteroid tint may suggest gall stone, especially if there is also localized peritonitis around the duct. Circumscribed peritonitis or peritonitis of the tubercular variety may exist and it may be quite impossible to differentiate the processes. Pain, dyspnœa, hiccough, and vomiting may be common to both conditions, and moreover, both conditions may be intertwined.

Rheumatism of the diaphragm is recognizable by its relation with the rheumatic diathesis; pain on respiratory effort may be acute and is felt over the diaphragmatic zone, and at the insertions of the muscle. In chronic pericarditis the symptoms may resemble diaphragmatic pleurisy, especially by the symptoms of dyspnœa and pain, over the costo-ziphoid region. I need not, however, develop the physical signs which should enable one in most cases to decide the existence of the former affection, but when the diaphragmatic pleura on the left side is concurrently affected, the differential diagnosis may be very difficult, or impossible.

The prognosis of diaphragmatique pleurisy is intertwined with the intercurrent pathological process, and in its acute forms has already been discussed. When the process is sub-acute or chronic, although adhesions may form, the powers of adaptation possessed by the pulmonary system are so great that the duration even of double diaphragmatic pleurisy may be indefinite. The most serious symptom in my experience is hiccough, which is especially uncontrollable in this relation.

REPORT OF A CASE OF EPILEPSY OF FORTY-FIVE YEARS' DURATION, WITH AUTOPSY.[1]

BY WALTER CHANNING, M.D.

THE patient, a female eighty-one years of age, died in February of the present year (1886). She was small in statue, of wiry, active build, and capable of enduring considerable physical strain. In old age she was lithe and active as a child, and possessed the characteristic of her family — of retaining the natural color of her hair, with few gray hairs, up to the day of death. She belonged to a long-lived family, a sister living to upwards of ninety-five, and another relative to over one hundred. She inherited no insanity, but some members of the family were nervous, impulsive, and quick-tempered. She was herself rather quick and impulsive in her feelings, and had such unusual ways of doing things that she was sometimes called eccentric.

She was married, had one child, and was in fair general health up to 1841, when she sustained a severe injury by being thrown from a carriage on to a stone wall, striking on her forehead. The point struck was in the middle of the forehead, about an inch above the supra-orbital arches, and exactly in the median line. An indistinct cicatrix at the point described has always been apparent on near inspection. It was round, and about the size of a half dollar. A relative states that the attending physician performed the operation of trepanning, or trephining, and the circular shape of the cicatrix, both of the scalp and skull, would seem to bear out the assertion that the latter operation might have been done. A later medical attendant says that he never heard of it, but the probabilities are that it was performed.

The accident was followed by symptoms of concussion, and for several weeks the patient was unconscious and delirious. She slowly recovered from the accident, not regaining her former physical strength. Up to the year 1859 she continued in fair health mentally and physically, though growing more peculiar and eccentric. During these twenty years she passed through the change of life.

In 1859 she had the first attack of *grand mal* now known to the friends. That she had previously been subject to seizure of nocturnal epilepsy in the form of *petit mal*, the statements of some observers and the change in her condition furnish strong presumptive evidence. The attack of 1859 was characteristic. Others occurring soon after made it necessary to have her always in the company of some one else, in order that no accident might occur. These attacks were accompanied or followed by slight local paralysis, and the mouth became permanently drawn to the right side. Mental irritability also began to develop, accompanied sometimes by excitement, and later by delusive ideas and violence.

She finally became unmanageable at home, and in 1867 she was taken to the McLean Asylum. The record book of the Asylum refers to the accident, and says that "sight was lost for some time after the accident. After she could read, the slightest pressure on the base of either eye made her blind. There was also paralysis of the auditory nerves, hearing returning first in one ear, then in the other. Speech was also impaired. She had been having the epileptic seizures for six years, and her general health had been poor. Sometimes she would have several during the twenty-four hours, then none for several days. Brown-Séquard had treated her, and for the year previous to admission, she had had no fits, but the general and mental condition had grown poorer. At admission seemed very feeble; speech was a little affected, there being a slight clipping of some words; the memory was weak; she had been excited at home, and turned against those about her." She remained at the asylum four months. During this time, she took forty grains of bromide of potass three times daily, and had only

[1] Read March 18, 1886, before the Boston Medico-Psychological Society.

one fit. She was discharged as practically recovered so far as the attack of mental trouble was concerned.

From the time of her discharge to the summer of 1871, she was well enough to be at home, though having occasional attacks. In September of that year she was seized with a succession of epileptic convulsions, which followed each other in rapid succession to the number of twenty-five. After these she was excited and violent, and was kept for three days in a camisole. She turned against her husband, accusing him of being in league with the servants to poison her. She was then sent to the asylum at her own request, remaining nearly two months. She took one hundred and twenty grains of the bromide of potass daily, and had only two epileptic seizures. She was quite comfortable when discharged.

In 1875 she again had numerous attacks of *petit mal*, which had occasionally shown themselves since her last discharge. Becoming violent and unmanageable, she was again admitted to the McLean Asylum in a more excited condition than at any previous time. She soon became quiet, but had seizures of *petit mal* at frequent intervals, combined with irritability and various insane ideas. She now began to make many and extraordinary demands, such as having an aurist, oculist, hair-dresser, chiropodist, female physician, etc., summoned immediately, and was extremely angry because her wishes were not immediately complied with. In the spring of 1876 she was discharged, being at that time somewhat better.

She was again admitted to the McLean Asylum in the summer of 1877 in about the same condition as at the last time, except that she was perhaps more violent, being brought to the asylum bound to an iron bedstead. She remained at the asylum until January, 1879, having periodical attacks of *grand* and *petit mal*, and growing mentally rather more feeble.

At this time she came under my care. On admission I made the note: "Her history points to attacks of nocturnal epilepsy, alternating with day attacks; reduced in flesh; complexion bad; pulse weak, 80; quite bright in conversation; memory fair; says she is very poor, and must save carefully; picks up threads wherever she sees them; wishes to do her washing, mix various strange drinks, etc." At that time mouth was drawn to the right side; there was no impediment in her speech; sight was good; heard well on the left side, not so well on the other side; walked naturally; face marked with numerous scars received probably in past epileptic seizures.

A few days after admission, a severe maniacal attack developed, following an attack of nocturnal epilepsy. She slept none at all at night; had on almost no clothing; kept on her feet constantly, and occupied her time in washing, dressing, greasing her furniture, tearing her clothing, etc. This attack lasted two weeks, and was followed by a period of comparative quiet, in which she drove out daily, took her meals at the table, etc. At this time (February, 1879), I made this note: "To-day, while talking, eyes became fixed; this was quickly followed by unconsciousness and slight convulsion (a tremor more properly), the latter lasting half a minute. For an hour after this seizure actions were peculiar and unnatural. After this time tired, but as well as before the attack."

In May, 1879, I made the note: "Attacks of *petit mal* average once or twice a week, and occur about one-fourth of times at night."

July, 1879, I entered in my record book: "Since the last report, has been through the usual states of excitement, depression, quiet and irritability. This morning had one of her seizures of *petit mal*, followed by mental confusion. She now (9 A.M.) shows no indication of such an attack, and, as is often the case, is brighter and apparently better after than before the seizure."

In August she was not so well again, and I wrote: "As usual in her excited state, makes a great variety of requests, and is with difficulty restrained from carrying out her wild projects. To-day she wishes to go to Hovey's and Pierce's to buy a great variety of presents; she wants mucilage, a box of cologne, ammonia for furniture polish, locks of various persons' hair to make ball ear-rings, currants to make currant jelly for her own house, perfumes of different kinds, patent medicines, etc. Must go to the tin-smith's, carpenter's and other places."

In September she was much depressed, sitting most of the time quiet and listless in her own room.

In October she had much improved. Took a natural interest in her surroundings, drove and walked daily, called on her friends, and appeared almost well.

In November, she had passed again into a state of excitement. At that time she intended to get up a national fair, for which she had arranged an elaborate programme, and she gave me a list of twenty articles to buy. She had also prepared a mixture of water, figs, sugar-wine, and cuticura soap, which she said she drank with great benefit herself, and insisted on all persons taking.

She had at this time an attack of *grand mal*, but it seemed to have no connection with the general excitement.

November 22d, I made this note: "Has continued to grow more excited since last report. She will talk somewhat as follows: Has thirteen questions to ask as there are thirteen States; has put water into bottle of salt three times three because she was married in '33; has put ammonia into vessels with finely cut-up hairs to dissolve them; has bought four kinds of perfumes, one drop of each she proposes to put into rockers of her chair; wants poetry she has composed arranged to the best music, and have it sung publicly, and with the proceeds help her fair; wants four paper-weights bought and given to four prominent poets, one monster weight for the State-house; wants handsome pedometer bought for each State in the country; wants her brother's watch exhibited; wants to see the carpenter, plumber, baker, caterer, her old servants and numerous other people; wants her carriage repaired, and will present $5.00 to each person who works on it.

The next day she said she would write a book equal to the Bible, from an inspiration she had the night before; was soaking her teeth in spring-water, spitting everything sweet into one vessel and everything bitter into another.

On the fifth of December following, she had a severe attack of *grand mal*, left side was almost motionless, then severely convulsed, convulsions extending to the entire body; left eye closed as she came out of attack; speech for half an hour after consciousness returned, indistinct; would constantly repeat the same words.

This attack was the worst one she had had up to that date.

In the course of two weeks she again became quiet and rational.

It should be stated that the sense of smell and taste seemed to be almost, if not entirely absent. This fact I did not discover until she had been under my care for some time. Her mouth was usually dry, and she often said she could never shed tears, which was a fact, as I never knew her to shed a tear in six years under my care.

In looking back over the year 1879, the patient's mental condition seemed to have presented many of the characteristics of *folie circulaire*, the periods of excitement and depression being very marked, and the latter followed usually by a period of comparative lucidity, and mental stability; each period was, to be sure, quite short, and in that respect differing from *folie circulaire*.

A remarkable feature of the case, was the accompanying epileptic phenomena, which sometimes produced mental perturbation, but not at all at other times.

I do not mean to say that all the symptoms of mental instability were not dependent on epileptic discharges, but as observed externally, they took the form of *folie circulaire*.

The years 1880 and 1881 were not particularly eventful, the number of epileptic seizures averaging about the same. The patient's mind weakened a little, but so very little that it was hardly noticeable.

There were in these years more severe attacks of *grand mal*. The periods of excitement were about the same; the quiet periods of longer duration.

All this time her general health was excellent; her appetite was good, and when at her best it was not easy to see that the strain of repeated epileptic attacks had affected her general condition. Very frequently she would say that she had never had a headache in her life, and could not imagine how it would feel to have a pain in her head.

In 1882 I noticed a change in the character of the maniacal attacks; instead of a prolonged period of excitement followed by depression, there was now a change on alternate days. In September, 1883, I wrote: "She is now emerging from a condition of alternate mania and melancholia occurring on alternate days. The symptoms of each form of disease are perfectly typical. One day she gives away everything, and is about to die; the next day there is the excitement and incoherent language of acute mania, with destruction of clothing, drinking of urine, etc."

The next record of interest was in February, 1883, up to which time she had improved. The alternating character of the disease grew less marked, and after several attacks of *petit mal* on January 11th, followed by great violence, she daily grew more rational.

In February I wrote: "Very rarely knows about epileptic seizures, but knew one was coming two nights ago; she says her vision was first affected, she saw a small rain-bow, which increased in size and seemed very beautiful, then this disappeared, and she felt a peculiar sensation in her abdomen in the region of the left ovary, which gradually grew higher and higher."

In May, 1883, I wrote: "Has been depressed and excited on alternate days. Slept very poorly every other night, and more irritable on excited days. Increased violence characterizes her advancing age. Has about two attacks of *petit mal* weekly, usually at night." Later in this month she had a severe seizure of *grand mal* preceded by several of *petit mal*. On coming out of the attack the right side was found to be motionless, with mouth drawn to the left and left eye closed; could not speak for several hours and then incoherently. The paralysis began to pass off in two days and was entirely gone in five days. Hallucinations of sight were marked at this time, though her mind was quite clear.

For three months following she was comparatively comfortable; then the alternating attacks began. In December, 1883, I wrote: "She is one day bright, active and quite rational, and the next stupid, depressed and inclined to think she will die immediately. On the bright day her appetite has been good, and on the depressed day poor. The night of the depressed day good; the night of the excited day not so good."

At this time she described the pre-epileptic aura, as "a face in a star, with one bright and one dull eye. The bright eye has numerous bright rays of light, like eye-lashes projecting from it." After this vision comes, as described before, a pain in the epigastric region.

In April, 1884, after a period of alternating insanity in February, and comparatively good health in March, she had an epileptic seizure followed by a temporary paralysis of the left side. She used meaningless words, generally misplaced, for some days after this attack.

In September of the same year, I wrote: "Since the above record, has had a variety of epileptic seizures, both *grand* and *petit mal*, and by day and night. Her memory and general intelligence have weakened considerably. She now lives much in the past, and often mistakes those about her for old friends. The right side is usually principally affected during a seizure, and her power of clear articulation has been permanently impaired. She finds it difficult to select the right word, and is much irritated if not understood. She has occasional days of great irritability and violence, when she savagely attacks her nurse."

October and November following were months of comparative calm, and she was able to go to her meals, and drive, and walk a little, though her mind was weakened, as above recorded.

In December she was again violent. She attacked and pounded her nurse, seized her by the hair, tearing it out in handfuls, and was very furious. She had only six characteristic epileptic seizures during the month, though numerous attacks of violence, suspiciousness, depression, and cheerfulness. Her condition was very unstable, changing almost from one hour to another.

During the year 1885, the tendency was very slowly, but steadily downward. She was then in her eighty-first year, and the weakness, or lack of rallying power of advanced age, began to show itself. The number of epileptic and violent attacks were also greatly increased over any previous year, and tended to further reduce her strength.

In January, after an attack of *petit mal*, she saw and talked to an imaginary dog, heard him growl and was afraid of him. The same day she was violent and attempted to bite, and bit her own hands. She seemed to think she was a dog herself, and later during the year, when much excited, she imitated the actions and noises of animals, principally dogs.

She also began to make imaginary letters and write

during this month, sometimes for an hour at a time, slowly going through the motions, dotting the i's, crossing the t's, and so forth.

On the 13th of January, there was cataleptic contraction of the arms. She would bend them at the elbow upward, and keep them bent until they were put down, then she would slowly raise them again.

On the 14th of January she saw a lion, and was afraid of him. She also made the motions of writing, and tried to spell the words. At this time she could not speak clearly, and some days had difficulty in walking.

On the 17th, she had an attack of *petit mal;* when she saw a dog, was very violent and called "murder."

She had a severe seizure of *grand mal* on the 27th, and thought she saw a bear. The next day another seizure occurred, when she saw a long dog, and tried to keep her feet away from it.

On the 30th, there were thirteen seizures, ten occurring in an hour and a half. Of these, two were severe *grand mal* seizures. On the 31st, there were one *grand mal*, and one *petit mal* seizure.

During the month of January, she had, altogether, twenty-three epileptic seizures, not including four severe attacks of violence, which were probably also due to epileptic discharges. There were not more than four quiet days. Nights were fairly good. No two days were alike. At different times in the same day, she was quiet, drowsy, depressed, irritable, suspicious, excited, and violent.

In February, between two seizures, thought she saw a black cat. She was not afraid of it, and tried to purr like a cat. During this month she had six epileptic seizures, and eight attacks of violence. The latter were only once near the time of an epileptic seizure, and then just before. They seemed to take the place of the epileptic seizures. There was more depression during this month, and more good days.

During March, there were three attacks of violence and thirteen epileptic seizures. About one-fourth of the days were quiet, and as natural as could be expected, with the gradual loss of mental power. One day she saw a dog behind a fence, and she tried to catch and pound him. The general character of the month was like that of February.

In April, there were three attacks of violence, and ten epileptic seizures. Most of the days she was drowsy, suspicious, or irritable. Speech was growing more confused, and she realized little that was going on around her. She walked with more difficulty than before.

In May, four attacks of violence and ten epileptic seizures. The month was about like April.

During June, there were seven attacks of violence and seven epileptic seizures, several of the latter being severe. After one of them, she talked about a cow jumping over a fence. Her mind was now quite feeble; she lived almost entirely in the past, her conversation referring to her own home and family.

July was an unusually good month, as she got out to drive on thirteen different days. She saw a gray mare during this month, and did some imaginary writing. She had two attacks of violence and six epileptic seizures.

August was a trying month with her, as she had sixteen epileptic seizures, many of them severe, and two attacks of violence. When excited, she would often bite, and scratch like an animal during this month.

In September, there were seven epileptic seizures, most of them severe, and two attacks of violence.

In October, there were three attacks of violence and twelve epileptic seizures. Most of this month, when quiet, she was in a dazed or drowsy condition. She was settling into this state more and more as time went on, and only roused partially from it. She was less noisy in her violence, and, on the whole, less violent.

During November there were five attacks of violence, and nine epileptic seizures, none of the latter of unusual severity. She was less dazed this month, and went to drive several times. She was unable to walk without assistance, and the right side was weaker than the left, and becoming more so. Her food she began to swallow with difficulty. She had bitten and growled like an animal several times, when excited, during the month.

In December there were no attacks of violence, and eleven epileptic seizures, two of these being severe. She had grown slightly more feeble during this month. The right side was weaker, and she had lost the power to masticate or swallow solid food.

Altogether, during the year there had been one hundred and thirty characteristic seizures and forty-two attacks of violence, which were of undoubted epileptic origin. If we add both kinds together, we have a total of one hundred and seventy two epileptic attacks, which was a much larger number than in any previous year, as before stated, though they had not been before so carefully observed and counted.

During the month of January, 1886, she had nine epileptic seizures and four attacks of violence. The last epileptic seizure on the 31st was very severe, lasting some time, and being followed by several attacks of vomiting and twitching of the right eye and side.

After this time she was not able to sit up, though placed on a sofa. She also swallowed with difficulty, the milk, etc., remaining in her throat. Most of the time she was in a stupor, breathing heavily, and sometimes with difficulty. She sank gradually, and died on February 12th.

The autopsy was made fifty-two hours after death by Dr. A. N. Blodgett, assisted by myself, and the report is as follows: —

The body is that of a woman, of spare figure and medium height. The relative proportions of skull to face, and of the face to body, are apparently normal. Upon the body is an old cicatrix, occupying a position in the median line, and three cm. above the line of the supra-orbital arches. Higher on the forehead, are the appearances of other old cicatrices. The scalp is normal; nowhere are any signs of depression or other abnormal conditions observed. The calvarium is thick and heavy, the frontal sinus is absent. The dura mater cerebralis is not unusually adherent to the calvarium, The convexity of the dura is the seat of four small grayish excresences, varying in size from three to six mm., and rising about one mm. above the general niveau of the surrounding surface. The superior longitudinal sinus is empty. The dura is much thickened, bearing a close resemblance in some parts, especially over both anterior lobes, to a thick aponeurosis. It is unusually adherent to the pia, and when separated from the latter, is seen to present a marbled, or rather an embossed surface, as it is perceptibly thickened, and much more opaque in those parts which correspond to the intervals between the cerebral convolutions. The pia is everywhere quite vascular, and firmly adherent to

the substance of the brain, from which it is difficult to separate it without injury to the cerebral tissues. About one hundred cc. of serous fluid is discharged from the cavity of the dura mater.

At a point corresponding to the cicatrix of the supra-orbital ridge, is seen on the inner surface of the skull, a surface about two cm. in diameter, which is the seat of a moderate, irregular hypertrophy, with three small, prominent bony protuberances extending about two mm. above the general surface of the bone around. From the posterior border of the crista Galli, and extending as far backward as the optic groove, is a surface ca. three cm. long by fifteen mm. broad, to which the dura mater and the substance of the brain are so firmly adherent that they cannot be separated without laceration. The normal surface of the ethmoidal plate has been replaced by a dense and firm layer of bone, in which the perforations of the ethmoid are not preserved. The surface of the body of the sphenoid is raised above the normal level, and is thickly covered by small, elevated projections, to which portions of dura mater are inseparably attached. The entire surface is injected, and presents the appearances of chronic, progressive, osseous hypertrophy. The brain was removed with some difficulty, owing to the softened condition of the anterior lobes.

The vertebral arteries were the seat of extensive atheroma, and the inner coats were very loosely attached to the outer, so that they were easily separable. The entire basilar artery was the seat of the same atheromatous change, which had here intruded upon the inner surface of the vessel, so that its lumen was reduced in diameter at least one-half. The same condition existed in both posterior communicating arteries, and was especially marked in the carotids of both sides. This was also the case in the anterior cerebrals, and the anterior communicating artery was found to be entirely closed, being reduced to the appearance of fibrous cord. Thus the entire "Circle of Willis" was the seat of extensive atheromatous disease, the lumen of the basilar artery was reduced one-half by the encroachment of the same pathological process, and the walls of the vessel were much weakened. The calibre of the anterior communicating artery was obliterated at one point, so that there was no possibility of arterial supply to the opposite side of the brain through this channel. The anterior cerebral arteries were the seat of numerous small, aneurismal dilatations, as were the middle cerebral arteries of both sides. This condition existed through the entire fissure of Sylvius, on each side, and was noticed also in the primary ramifications of the distributing branches.

The frontal convolutions were flattened, the gray matter was thinned upon its periphery, and the convolutions presented the appearance of being subject to considerable pressure.

The ventricles contain but the normal amount of fluid, the consistence of the brain-matter is normal, and there is no appearance of pathological changes in these parts of the brain. Sections were made through the thalamus optici and through the entire hemispheres, as well as through the cerebellum, without discovering any notable signs of disease. Portions of the choroid plexus showed circumscribed patches of grayish color, due, apparently, to fatty changes of limited area.

Diagnosis ex Sectione. Pachymengitis circumscripta. Hypertrophea durae mat. Meningitis subacuta chronica. Atheroma arteriarum omn. Atresia arteriae basilaris cerebri. Endarteritis obliterans arteriae ant. com. Aneurisma circumscripta mult. Encephalitis circumscripta chronica. Hypertrophea basis cranii in os. front. et. sphen. med.

This case presents many features of interest, only a part of which I can consider this evening. The long duration, forty-five years, and the period of life which it covered are unusual. Few individuals have sustained so many and such severe attacks without succumbing much earlier.

No doubt the psychical form existed for the first twenty years after the accident, probably occurring as epilepsia mitior, or *petit mal*, and as nocturnal or larvated seizures. As time went on, the motor zones, as well as other portions of the brain, became more and more irritated, giving rise to the attacks of epilepsia gravior. That there is no pathological difference in the two forms, would seem to be borne out by this case. Either one was apt to occur, or one ran into another, and there was no regularity or periodicity to any of the attacks. It can only be said that every few days, the number of times increasing as the disease progressed, there seemed to be a necessity on the part of the brain to bring about a discharge to restore its equilibrium. As has been stated by Seppilli in his experiments on animals, and other authors in regard to man, the intensity of the attack may be entirely different at different times in the same individual. It may be diminished, abolished, or exaggerated under the action of various causes. The attacks depend largely on the excitability of the cerebral motor centres.

The attacks of violence to which I have referred as being of epileptic origin, are interesting as being one of the substitutive forms of epilepsy, and resembling or similar to those occurring in cases of larvated epilepsy, so-called for want of a better name. Had the patient above described belonged to the criminal classes, or had her social environment been lower and attended by a severe and anxious struggle for the means of living, the automatic and unconscious act of violence might have taken a homocidal or suicidal direction. Echeverria[2] quotes Lasègue, who pointed out the difference between the impulsive outbursts of ordinary insanity and epilepsy, as saying that unconsciousness stands prominently as the characteristic, distinctive of any act of violence perpetuated during the manifestations of the epileptic neurosis. "In either case," Echeverria says, "the original source of the transient fit is a morbid conception, whether impressed upon the sensorial regions of the brain by a precursory real emotion, or outer imitation, . . . or by some subjective inner feeling, the offshoot from a delusional groundwork that brings forth the excitation of sensory motor processes concerned in the insane abrupt act, automatically accomplished and elaborated in both cases in a coherent, logical manner, which necessarily involves a more or less considerable degree of deliberation." These last words are not correct as conveying the right idea of many of my patient's acts of violence, though the general explanation of the act seems extremely apropos. There were, however, attacks where a certain amount of coherence and deliberation were apparent. Thus on one occasion the patient got out of her window on to the roof of a little piazza. She was obliged to first place a chair on the roof, then with great care to step on to it, and then down. A very slight jar would have thrown her on to the ground. When once on

[2] Journal Mental Science, 1885.

the roof she felt she had accomplished her object to get the advantage of her nurse, and she remained quiet until brought back.

The varieties of insanity displayed in this case were extraordinary, and each kind was typical. Some of them occurred directly in connection with the epileptic attack, but others, as has been before stated, seemed to be independent, and the two varieties of symptoms, namely, those caused by the epilepsy and those caused by other exciting cerebral conditions, seem to run along together, or to jar against each other, producing many peculiar complications. In view of the extensive and peculiar post-mortem appearances, it is more easy to understand how this was possible.

The autopsy seems to show that the original injury was followed by an acute meningitis, which degenerated into a chronic meningitis, and the enormous hypertrophy, which is apparent on inspecting the dura mater is conclusive evidence of this fact. In this connection the following concerning the dura mater is of interest:

C. K. Mills, M.D., and J. W. White, M.D., report a case of epilepsy in which the operation of trephining was performed, and speak of the general nature of the spasms, which were not localized, nor confined to one limb nor one side of the body. They think the spasmodic seizures "were probably due to irritation of the dura mater, what might be called dural, or meningeal spasms. They were not due to irritation of the cortical motor zone, the form of spasm sometime spoken of as Jacksonian epilepsy. Lesions of the motor cortex cause disorders in the opposite side of the body; irritative lesions cause monospasm, or unilateral spasm of the opposite side.

The researches of H. Ducat[2] on cerebral traumatisms, have thrown considerable light on the rôle which the dura mater and its nerves play in these cases. Irritation of these branches of the trigeminal, or fifth pair of nerves which go to the dura mater, produces in addition to hyperæsthesia, pain and vasomotor disturbances, reflex spasms of peculiar character. Strong, powerful stimulation of the dura mater continued and developed was shown in certain physiological experiments of Bochefontaine to determine movements in both sides of the face, in the neck, and all four limbs. The movements of the limbs on the same side were more energetic than those on the opposite side.

The insane condition, apart from the epileptic, could be accounted for by the flattening of the frontal convolution, the thinning of the gray matter upon its periphery, and the indications of pressure.

The osseous hypertrophy of the middle portion of the sphenoid and ethmoid bones was remarkable. There was extraordinary roughening, and the appearances were similar to those that might be found in an old fracture. Not that any fracture had ever existed, but it seemed as if the force of the original blow had been projected backward and centred at this point, resulting in chronic inflammation, both of the meninges and bone. And it further seemed that this inflammatory trouble and the extraordinary growth and adhesion of the dura mater to the bone had gradually interfered with the circulation of the blood, through the circle of Willis, being in part the occasion of the thickening and occlusion of certain of its component vessels.

The nearness of the tempero-sphenoidal lobes may account for the loss (in part or in whole, it was not possible to determine which), of taste and smell, these lobes being given by Ferrier as the seat of these senses.

A further question which suggests itself is as to whether the occlusion of the anterior communicating artery and an evident degree of softening of the frontal convolutions had a bearing on the weakness of the right side?

RECENT PROGRESS IN OTOLOGY.

BY J. ORNE GREEN, M.D.

THE REMOVAL OF OSSEOUS TUMORS FROM THE EAR.[1]

THESE tumors are of two kinds, rapidly-growing, spongy osteomata of slight density, and the typical ivory exostoses or hyperostoses. The former is stated to be the more common form and is usually pedunculate, and of much greater vascularity than the ivory growths. Scrofula, rheumatism, gout, and syphilis, have been heretofore considered as predisposing causes on most unsatisfactory evidence, the author thinks, but believes that most frequently they originate in the active inflammatory processes accompanying chronic suppuration of the middle ear, which produce periostitis. Microscopically, the osteomata show Haversian canals bearing bloodvessels from the periosteum, with intervening, concentrically-placed lamellæ and bone-corpuscles, while the ivory hyperostoses consist of extremely dense, and but slightly vascular, osseous tissue, similar in hardness to dentine, and more compact than the temporal bone, with lamellæ not disposed concentrically around vessels, but running parallel to the surface. Where suppuration has not existed, the author thinks that slight, long-continued irritation of the meatus, such as may result from daily bathing in salt water, may be a cause of these growths.

In regard to treatment, an arrest of the tympanic suppuration is first necessary before attacking the osseous growth. The spongy osteomata can frequently be removed by an écraseur, dental forceps, or elevator; for the larger and more solid growths, the author considers the dental engine the only instrument which can be safely recommended. He uses to protect the deeper parts of the ear, a spoon-like, steel guard, the pattern of which is taken first in thin copper, and adapted to the particular case, so as to pass by the side of, and behind the exostosis. A small drill is then applied near the top of the growth without previous removal of the skin, and this opening gradually enlarged by increasing the size of the drills till the growth has been destroyed. Several operations are often necessary before the whole tumor is removed. Three assistants are necessary; one for the anæsthetic, one to work the engine, and one to hold the guard. The author reports fifteen cases operated upon successfully in this manner.

In two varieties of these tumors, the author considers no operation should be attempted. It is not requisite where two tumors from opposite walls come in contact, leaving a triangular space either above or below; for their contact prevents their further growth, and although deafness may result from the closure of the small opening by cerumen, this can be readily cleared away. It may be unjustifiable, on account of the risks of the operation where the growth is ivory-like, and situated in the deepest part of the meatus.

[1] By George P. Field, M.R.C.S. British Medical Journal, February 20 and 27, 1886.

The conclusions of the author are "(1) that aural exostoses must not be considered as at all necessarily the outcome of gout, rheumatism, or syphilis; (2) that their origin can, with strong probability, be attributed in many, if not in all cases, to some preceding local irritation; (3) that they can be safely and most effectually treated by drilling, when a suitable guard is employed to protect adjacent structures; (4) that their speedy removal is indicated whenever they hinder the elimination of secretions and discharges from the auditory canal, cause pain by pressure, or impair or prevent audition."

OTHEMATOMATA.

Virchow,[2] who had asserted[3] that he had never seen a pankratiastic ear in a healthy man which had been brought on by violence, now acknowledges that he has seen such a one in a Japanese wrestler, which was brought on by striking the side of the head against the opponent's chest.

Gudden had, twenty-five years ago, taken the ground that all othœmatomata were of traumatic origin. Franz Fisher, however, observed spots of proliferation, and softening in the cartilage of the auricle, which he regarded as the important changes predisposing to these tumors. Virchow had already confirmed these observations of Fisher, but now acknowledges that while this structural predisposition exists in many cases, in certain other cases the tumors have a purely traumatic origin, as in this Japanese.

TUBERCLE BACILLI IN THE EAR.

Eschle, Voltolini, and Trathan have already recognized tubercle bacilli in the otorrhœa of phthisical patients, but Habermann[4] has now found them in the tympanic tissues.

In a woman aged thirty-two, whose autopsy revealed tuberculosis-pulmonum and tuberculosis granularis subacuta universalis, he found the left tympanum filled with caseous pus containing large numbers of tubercle bacilli, the tympanic mucous membrane hyperæmic and swollen, infiltrated with small cells, which had penetrated into the bone, and this infiltration showing, in spots, caseous masses. In these miliary collections, and also in the diffuse infiltration, abundant tubercle bacilli were found. Similar changes were seen both in the mucous layer and the membrana propria of the drum-membrane. The infiltration was most marked at the lower edge of the drum-membrane, where the mucous layer and membrana propria had ulcerated. Habermann considers it a case of infection from the sputa in coughing.

STATISTICS OF OTORRHŒA ACCOMPANYING TUBERCULOSIS OF THE LUNGS.

Moldenhauer examined the records of the Medical Clinic at Leipzig, and found that of two hundred and ninety-four phthisical patients received, in only seven was suppuration of the ears noticed which could be referred to the general disease. This gives a percentage of 2.4, whereas the laryngeal diseases of a tuberculous nature amounted to twenty-six per cent.

DISEASE OF THE LABYRINTH IN CEREBRO-SPINAL MENINGITIS.

Accurate contributions to the pathology of the labyrinth are so rare that the following dissections of the labyrinths in a case of cerebro-spinal meningitis are particularly valuable.

It is reported by Steinbrügge[5] and was in the case of a man aged twenty, who died on the seventh day of his illness, and the autopsy confirmed the clinical diagnosis of cerebro-spinal meningitis. Testing of the hearing was impossible during life on account of the comatose condition of the patient.

Microscopically the left meatus auditorius internus was filled with a jelly-like exudation, as was also the entrance of the aquæductus cochleæ; the neighborhood of the aquæductus vestibuli showed small ecchymoses. The meatus externus, drum-membrane and tympanum were normal.

Microscopically in the left labyrinth between the nerve-trunks and their arachnoideal sheaths and also between the nerve-fibres were collections of cells, many of them resembling pus corpuscles, others larger with coarsely granular contents, and still others round and called ring-cells; there was great injection of the bloodvessels between the nerve-fibres but the fibres themselves showed no changes. The aquæductus cochleæ was filled with cellular masses and in several fortunate sections Steinbrügge was able to follow the passage of the pus through the aquæduct into the cochlea. The scala tympani contained collections of pus-corpuscles and "ring-cells" and the periosteum was in places loosened, but the scala vestibuli showed only the detritus of a coagulated exudation and no pus. The only changes in Corti's organ were hyperæmia and extravasations of blood. The vestibule showed less inflammatory changes than the semi-circular canals; in the upper and posterior canals there was very marked destruction, the bone deprived of periosteum and the canals filled with necrotic masses of bony particles, coagulated exudation and periosteal tissue. The facial nerve showed the same changes as the acoustic, and the right labyrinth the same conditions as the left, but in a lesser degree.

The author is not inclined to ascribe to the simple penetration of the pus into the labyrinth from the meninges the pathogenetic importance which used to be given it, for he regards the general disease as due to an organized specific virus, probably the coccus already described by Leichtenstern, which, being very minute, can penetrate the labyrinth from the cerebro-spinal fluid more easily than the pus-cells can, and there sets up necrotic processes, even without pus, which destroy the delicate labyrinthine structures.

The total and permanent deafness, frequently the result of cerebro-spinal meningitis, he regards in most cases not as a paralysis caused by the pressure of the exudation on the nerve-trunk, as has been often assumed, but due to the destruction of the terminal nerve-fibres in the labyrinth. The exudation which undoubtedly occurs in and upon the nerve-trunks of both the acustic and facial nerves is absorbed, although in exceptional cases there may be cicatricial contraction of the neurilemma and consequent impairment of the function of the nerve.

ABSCESS OF THE BRAIN FOLLOWING OTORRHŒA, CURED BY OPERATION.

This is the second successful case of evacuation and cure of an otorrhœal abscess within the cranial cavity by operation, the first being reported by Schondorff.[6]

[2] Virchow's Arch., 101, p. 357.
[3] Onkologie, 1, 138.
[4] Prager Med. Wochenscrift, No. 6, 1885.
[5] Zeitschrift für Ohrenheilkunde, xv, 4.
[6] Archiv. für Klin. Chirurgie, 1884.

The present case is reported by Truckenbrod[7] of Hamburg. A man of twenty-eight with an otorrhœa on the left side, of eighteen months' duration, showed pyæmic symptoms with tenderness of the bone, for which the mastoid process was opened and at the depth of five millimetres, fœtid caseous pus was evacuated.

Temporary relief resulted, but fourteen days after there was a return of the fever, with right facial paralysis, aphasia, and amnesia, with œdema above and behind the ear. Three centimetres upwards and backwards from the meatus was a carious fistula which was enlarged into the cranial cavity and offensive pus was seen exuding between the dura mater and the bone. After further exposure of the dura mater an exploratory puncture showed pus and on incision of the dura a teacupful of extremely offensive pus was evacuated from a cavity the size of a small orange. This was washed out with a one per cent. sublimate solution, drained and the wound dressed with corrosive sublimate bandage.

The fever subsided in a few days, the aphasia slowly improved, in ten days the patient was out of bed and in six weeks left the hospital. Two months after a return of fever required another puncture and further drainage of the abscess and this was followed by a rapid and perfect healing. Five months after the patient remained well, and was following his profession of an architect, only showing occasionally a momentary loss of a word.

SPASM OF THE GLOTTIS IN RICKETS,

by James T. Whittaker, M.D., Cincinnati, O.

The author emphasized the fact that this accident belongs almost exclusively to rickets and dwelt upon the value of recognition of this fact, because rickets is, generally speaking, a curable disease, and the spasm of the glottis disappears with the successful treatment of its cause, while treatment addressed to the larynx directly, remains without effect.

The speaker next quoted from a number of authorities to show that this relation between the two affections is not so universally recognized in this country and England, as in Germany and France. The two latest authors of text-books in Germany, Strimpell and Sichorst, declare, one that two-thirds and the other that nine-tenths of all spasm of the glottis depends upon rickets.

Spasm of the glottis is often the first sign to unmask rickets, for the other evidences of the disease are often attributed to other causes. Thus general malaise is attributed to dentition, intestinal catarrh to errors in diet, fever and sweating to malaria, bone deformities to premature efforts upon the feet, etc.

Spasm of the larynx indicates the stage rather than the degree of rickets, in that it occurs mostly in cases of rapid advance of the disease and does not appear in cases of slow progress. So in the spring and fall, when rickets advances in leaps, spasm of the glottis has occurred in epidemic form.

The essayist discussed next the various theories of rickets which continue to elude investigation to a degree characterized as exasperating, but facts accumulate which go to give it place among the chronic infections. The exemptions of hot climates and mountains, Iceland, the Faroe Islands, the complete immunity of Davos, notwithstanding the improper feeding and improper hygiene of sucklings at these places show that faults in diet cannot be the cause of it, and the symptomatology of it fits better among the chronic infections produced by specific causes.

Spasm of the glottis in the absence of any constant lesion falls among the neuroses. The question as to the reflex or direct character to the irritation producing it was decided after a review of the evidence in favor of the latter, and since Rosenbach has demonstrated the micro-organism of tetanus which often begins with and may go no further than trismus, the maintenance of a mycotic theory for the laryngospasm of rickets may be adopted as the best provisional explanation. The mode of onset and character of the accident were next detailed and the symptomatology illustrated with a typical case.

The inefficiency of anæsthetics and all direct means of treatment, as by intubation, tracheotomy, etc., were mentioned next, and douches, flagellations, electricity, cold air, direct appeals to the skin on the first appearance of attack, were described as the best means of combating and more especially of preventing the attack. Cod liver oil, and more especially phosphorus which may be looked upon almost in the light of a specific were considered the best means of speedily relieving the rickets, and thus removing the cause of the laryngeal spasm. It has the most favorable prognosis of all kinds of laryngospasm, as Monte lost but eight of three hundred and twenty-nine cases.

DISCUSSION.

Dr. A. Jacobi, of New York. This is a subject in which I am much interested. As has been said, this is almost always due to rickets. Its causation may be the pressure of the enlarged glands about the neck irritating the nerve. When the rickets disappears, the spasm of the glottis also disappears. The disease may be primary or secondary. In forty-nine out of fifty cases of spasm of the larynx, the cause is rickets, and in forty-eight of these it is rickets of the cranium and of the meninges of the brain. When the cranium is opened we find congestion. Cranio-tabes need not be developed to any marked extent. Where we have a succulent cranium, we have succulent meninges and a succulent brain. There is meningeal hyperæmia and meningeal effusion in such cases. In regard to prognosis, if you have six weeks during which to carry out proper treatment, you may be sure that the child will lose its laryngismus stridulus, but during that time, the child may die in an attack.

Dr. William Pepper, of Philadelphia. In a case of spasm of the glottis in whooping-cough seen recently with Dr. Morris J. Lewis, the attacks were so severe that on several occasions, the child apparently died. Nitrite of amyl was successfully used for the relief of these attacks. It was found that a combination of one part of nitrite of amyl with nine of sulphuric ether gave the best results.

Dr. Jacobi. I have recently used nitro-glycerine

[1] Continued from page 616.

[7] Zeitschrift für Ohrenheilkunde, xv, Nos. 2 and 3.

for a similar purpose; I have used it in inflammatory hydrocephalus in young infants, and I believe with fair results.

NOTES ON SOME CASES OF DIAPHRAGMATIC PLEURISY,[2]

by EDWARD T. BRUEN, of Philadelphia.

DEMONSTRATION OF BACTERIAL CULTURES FROM A CASE OF MYCOTIC ENDOCARDITIS IN MAN, AND OF SPECIMENS SHOWING THE EXPERIMENTAL PRODUCTION OF THE DISEASE IN RABBITS,

by T. MITCHELL PRUDDEN, M.D., of New York.

The communication was a preliminary one, the experiments not having yet been completed. For some years the presence of bacteria has occasionally been observed in the cardiac and peripheral lesions of malignant ulcerative endocarditis. It has, however, been found that not only not all cases of acute vegetative endocarditis, but not even all cases of ulcerative endocarditis present bacteria in their lesions. The speaker thought that the anatomical distinction was not clearly enough drawn between simple and malignant ulcerative endocarditis. Of eleven cases of well-marked ulceration of the valves which he had studied within the past four years, only four showed the presence of bacteria.

In only one case of malignant ulcerative endocarditis was he able to isolate and study the living bacteria. This was a case of pyæmia following cuneiform osteotomy for club-foot. The tests applied showed the bacterium to be the staphylococcus pyogenus aureus.

The experiments on animals were then described, and the following conclusions were drawn. If we sum up the results of combined morphological and biological examination of the cases thus far studied, we find that the sphero-bacteria found in the cardiac and peripheral lesions were the stryphococcus pyogenus and the staphylococcus pyogenus aureus and albus, either alone or together.

The intravenous injection of either of these or a mixture of them, into the rabbit after mechanical or chemical injury of the endocardium is capable of inducing lesions strictly analogous, if not identical with those found in malignant ulcerative endocarditis in man. The coccus sepsis of Nicolain is capable of producing similar results.

Neither the endocardial injury nor the intravenous injection of bacteria alone, are sufficient to induce the the cardiac lesion. Both are necessary.

As far as the observations go, they tend to confirm the view that malignant ulcerative endocarditis is simply one of the forms of pyæmic lesion determined by the predisposing conditions of the endocardium. Whether or not there are other forms of the disease induced by other species of bacteria or having no relation to bacteria at all, are questions which are more likely to be settled by experiment than by conjecture.

Adjourned.

FRIDAY.— SECOND DAY.— MORNING SESSION.

The first paper was by W. T. COUNCILMAN, M.D., of Baltimore, on

CERTAIN ELEMENTS FOUND IN THE BLOOD OF MALARIAL FEVER.

It has long been known that changes in the blood occur in this disease. It is now known that in the red corpuscles, there are certain bodies which appear to be living organisms, and these occur only in this disease. These are found by taking a drop of blood and spreading it on a slide, so that there shall be but a single layer of corpuscles. These are stained with a weak solution of fuchsin. The nuclei of the white corpuscles will be intensely stained, the red slightly stained, and in some of the red corpuscles will be seen brightly stained bodies of irregular shape. These exhibit distinct amœboid movements. The variety of their changes of form was illustrated by drawings. Certain hyaline bodies also found were described. The speaker then referred to the work of other investigators in this field, and gave a review of the results which they had obtained.

TETANY,

by H. M. LYMAN, M.D., of Chicago.

Tetany may be defined as a more or less generalized, intermittent, usually tonic convulsion of the muscles of the limbs and trunk, sometimes involving the face and visceral organs, usually painful, but never attended with loss of consciousness. The disorder is functional, and is based upon no distinctive pathological lesions of the central nervous organs. It is manifested in a series of attacks, which occur at intervals varying in length from a few hours to weeks, or even months. These attacks are sometimes very abrupt in their onset; oftentimes they are preceded by headache, disturbances of the digestive organs, and various disorders of sensation in the skin and muscles, after which the characteristic paroxysms appear. During the paroxysms, the flexor muscles are usually the seat of contracture, but sometimes the extensor muscles of the limb are principally involved, so that the fingers and toes may be spread apart and extended. Sometimes the flexor muscles about the elbow are principally involved. Single muscles alone may be attacked. These contractions may be very energetically developed, with considerable pain, or they may be sluggish and painless. The pain is usually due to the muscular spasm, but neuralgia may be associated with the cramp, and the skin may sometimes become inordinately sensitive. The pain may, at other times, become located about the joints, which then present the characteristic appearance of rheumatism. Diminished sensibility in certain parts of the body may be sometimes observed during or after an attack. The special senses are rarely disturbed. The action of the heart is seldom changed, except by transient palpitations; and only when the respiratory muscles are involved in severe cases, is there any difficulty in breathing. A febrile movement is only remarked when inflammatory complications are present. Electrical tests indicate an increased excitability of the motor nerves, which may sometimes even include the facial nerves.

The disease is rarely fatal, although death has occasionally resulted from prolonged spasm of the respiratory muscles. The duration of the disorder is quite variable, and relapses are rather frequent.

Having no relation with any particular lesion of the nervous centres, tetany appears to be dependent upon a functional instability of the nervous and muscular organs. This instability is usually the result of diseases that affect the organs of digestion and the processes of nutrition. Congenital weakness, and the period of debility that precedes or follows any acute disease, may then afford occasion for the manifestation of this particular disorder.

[2] See page 1.

The principal diseases with which tetany may be confounded, are tetanus, organic diseases of the brain and spinal cord attended with contracture, epilepsy, especially the so-called cortical or Jacksonian variety, professional cramp, and spasmodic phenomena of ergotism.

The treatment must be directed in a general way against the fundamental instability of the individual constitution. Mild attacks require no special therapy, but severe attacks often demand the energetic use of narcotics and anæsthetics for their relief.

DISCUSSION.

Dr. John T. Carpenter, of Pottsville. I have one observation to make bearing upon the causation of this affection, and that is with reference to its association with septic poison. The first time I noticed this association was in a child two years of age, with an abscess of the buttocks. The muscles of the eye and of one arm and hand were affected. There was no clonic spasm. Later, the muscles of the jaw became involved. The mouth could not be opened. Under chloroform, the jaws were separated and a piece of soft wood placed between the teeth. To my surprise, the entire spasm relaxed in the course of five minutes. The disease, however, progressed, and the child died. I attribute the condition to absorption of poison from the abscess. In studying my cases of tetany, particularly of the milder variety, I think that I am able to trace them to septicæmia.

Dr. A. Jacobi, of New York. In a large number of these cases, we have reason to believe that there is meningeal hyperæmia. An occasional cause which has not been mentioned is masturbation. This I have seen in one case, in which the attacks always followed masturbation. The attacks had not occurred before the age of puberty. We know that severe nervous attacks may come on during sexual excitement. I recall the case of a young woman who was thrown into catalepsy every time she cohabited, and had the attacks only at such times.

PERFORATING INFLAMMATION OF THE VERMIFORM APPENDIX, WITH SPECIAL REFERENCE TO ITS EARLY DIAGNOSIS AND TREATMENT,

by Reginald H. Fitz, M.D., of Boston.

A historical statement was made of the origin of the terms typhilitis, perityphilitis, and perityphilitic abscess. The want of exact agreement as to what was understood by these terms was emphasized. Attention was called to the importance of bearing in mind that in the vast majority of cases, the primary disease was an inflammation of the cæcal appendix. The term appendicitis was preferred to typhilitis, as avoiding the possibility of a misunderstanding, and as localizing the disease in its usual place of origin.

The paper was based upon an analysis of two hundred and fifty-seven cases of unquestionable perforating ulcer of the appendix, and of two hundred and nine cases diagnosticated as typhilitis, perityphilitis, and perityphilitic abscess. In the latter series, the diagnosis was clinical, not anatomical.

The important features in the etiology of appendicitis were considered, also the limitations as to sex and age. It was found that the disease occurred most frequently among previously healthy youths and young adults, especially males; that a fæcal concretion or foreign body was present as a local cause in more than three-fifths of the cases. Attacks of indigestion and acts of violence, especially when indirect, were exciting causes in one-fifth of the cases. The action of these causes was favored by a constipated habit, or by congenital or acquired irregularities in the position and attachment of the appendix.

The first characteristic symptom of a perforating appendicitis was found to be a sudden, severe, abdominal pain. This occurred in eighty-four per cent. of the cases, and usually in the right iliac fossa, where tenderness could always be found, even when the pain was referred to some other locality. The pain was attributed to the actual perforation or the detachment of fresh adhesions.

Fever was the next characteristic symptom, and occurred in the course of twenty-four hours. Finally came the swelling which made its appearance in the course of three days.

The chief source of danger from the appendicular peritonitis arose from its becoming generalized. Such a result followed most frequently between the second and fourth days. More than two-thirds of the patients died during the first eight days and two-thirds of these between the fourth and eighth days inclusive.

The question of a differential diagnosis was then discussed. The termination in resolution was referred to. It was considered to take place in about one-third of the cases as approximately determined from the recorded cases of typhlitis and perityphlitis. Even resolution might be undesirable since the number of cases of recurrent disease is considerable, and might have been prevented by appropriate treatment.

The reader recommended at the outset, the opium treatment with rest and a liquid diet, the food being given in small quantities, frequently repeated. If it became evident that general peritonitis was imminent at the end of twenty-four hours after the sudden intense pain the appendix should be exposed and removed. Usually the symptoms were not so urgent that the appearance of the swelling could not be awaited. Although Willard Parker advised that the abscess might be opened as early as the fifth day, the practice has been to operate at a later date. Forty-seven per cent. of the cases were operated upon in the second week and twenty-six per cent. after the third week.

More favorable results in the future were to follow the earliest possible opening of the swelling. This in most instances was at the outset, a sac formed by a circumscribed peritonitis. It was usually present on the third day of the disease, dating from the pain, its first marked characteristic symptom. Negative results from a diagnostic puncture did not contraindicate the operation.

DISCUSSION.

Dr. William Pepper, of Philadelphia. I desire to relate two cases which bear upon this point. On Saturday last, while making a post-mortem examination for another purpose, I examined the appendix, as is my usual custom. The appendix contained two hard concretions looking like date-seeds and some hardened fæces. These must have been there for a long time, but there were no evidences of inflammation. It was clear that the presence of these masses had been tolerated for a long time without exciting any local trouble.

A few days before that, I made a post-mortem examination in the case of a man aged forty, who for

years had sacrificed every interest in life for his business. On Monday he had some nausea and vomiting for which he took a laxative. He returned to his home in the evening feeling badly and sent for a physician. There was vomiting, some fever. There was marked abdominal pain which was relieved by the use of opium suppositories. On the fourth day I examined him, but could detect no tumor in the right iliac region. There was frequent and free micturition. This symptom would have a bearing upon the possible existence of intestinal obstruction. Another marked symptom was tenesmus. Several large stools had followed the laxative. Enemas of warm oil produced no evacuation. Rectal examination gave a sense of indistinct dulness, but showed no hard tumor. Collapse set in on the fifth day and the patient died on the seventh day.

The question of laparotomy was carefully discussed. It was not performed at first because of the uncertainty of the diagnosis, and later when the diagnosis became evident, because of the condition of collapse. At the autopsy no peritonitis was found. There was a contraction of the ascending colon at its junction with the transverse colon, but not sufficient to cause complete obstruction. A circumscribed abscess was found around the vermiform appendix, which was dilated. There was a large perforation. No concretion was found.

These cases have impressed upon me the view of which I am convinced, namely, that perforation of the appendix is only the explosion of an old catarrhal appendicitis; that it is not an acute idiopathic affection.

The diagnosis in these cases is a matter of great difficulty in the early days, except where it is associated with considerable pericæcal inflammation.

I agree with Dr. Fitz, that early operation gives the only chance of saving the patient. I should not think the third day any too soon. The difficulty is to arrive at a sufficiently clear diagnosis at that early date to justify laparotomy as an exploratory operation.

DR. J. T. DANA, of Portland, Me. I am sure that it is not rare to find inflammation of the appendix as a latent affection. In a case which I recently saw the first symptom was the occurrence of general peritonitis. By exclusion I made the probable diagnosis of perforation of the vermiform appendix. The case resulted fatally in seventy-two hours. At the autopsy general peritonitis was found, and there was an opening in the appendix through which a concretion had escaped. A second was found within the appendix. There had been no previous symptoms to call attention to disease of the appendix. This illustrates a class of cases of which I have seen not a few.

DR. A. L. LOOMIS, of New York. This is a positive paper, and it gives us some positive data on which to base our modes of action in this condition. From my experience I should say that it was impossible in the majority of cases to make an early diagnosis by the ordinary means of diagnosis. Of the symptoms given by the patient the most certain indication seems to be given by the occurrence of a chill. When pain is marked it will usually be localized in the left side, but not necessarily. Recognizing the importance of the early diagnosis, I decided several years ago in such cases to put the patient under the influence of an anæsthetic and examine by the rectum and externally. In the first case that I adopted this plan, the chilly sensation had preceded my visit twenty-four hours. By bi-manual palpation, I satisfied myself that there was an increase in the region of the appendix. I expressed the opinion that perforation had occurred and recommended operation. This was refused. Peritonitis set in within twenty-four hours and the patient died. In two other cases I have made the diagnosis by the same plan. It must be remembered that the vermiform appendix does not occupy the same position in all individuals.

As soon as the diagnosis of perforation is made out, the operation should be performed.

DR. E. G. JANEWAY, of New York. These cases of appendix disease may be divided into three classes. In one an inflammatory process of the cellular tissue, with or without the formation of pus is established. This may go on to recovery. If pus forms, surgical procedures should be resorted to. In another class of cases there is a circumscribed collection of pus in the peritoneal cavity. In this class operation should be resorted to as soon as the presence of pus is determined. In the third class we have as a result of the perforation of the appendix, general peritonitis.

The pain and tenderness in these conditions are not always on the right side. As has been said, the position of the appendix is not constant.

In these cases you can generally find on careful examination in the region of the cæcum, at some point a feeling of deep-seated induration, and at this point there is tenderness.

The Association then went into

EXECUTIVE SESSION.

The officers elected for the ensuing year are as follows: —

President, Dr. S. Weir Mitchell, of Philadelphia.
First Vice-President, Dr. Francis Minot, of Boston.
Second Vice-President, Dr. R. Palmer Howard, of Montreal.
Secretary, Dr. George L. Peabody, of New York.
Recorder, Dr. James T. Whittaker, of Cincinnati.
Treasurer, Dr. W. W. Johnson, of Washington.
Council, Dr. William H. Draper, of New York, Dr. Robert T. Edes, of Boston, Dr. H. M. Lyman, of Chicago, Dr. Samuel C. Busey, of Washington, Dr. Frederick C. Shattuck, of Boston, Dr. William Osler, of Philadelphia, and Dr. W. W. Welch, of Baltimore.

The proposition with reference to the formation of

THE ASSOCIATION OF AMERICAN PHYSICIANS AND SURGEONS,

was presented and approved. The following committee was appointed to confer with other organizations: Drs. William Pepper, of Philadelphia, Robert T. Edes, of Boston, R. P. Howard, of Montreal, James T. Whittaker, of Cincinnati, and Francis Delafield, of New York.

(To be continued.)

THE NEW HAMPSHIRE MEDICAL SOCIETY.

THE ninety-sixth annual meeting convened at Concord, N. H., June 15, 1886, the President, George A. Crosby, M.D., of Manchester, N. H., in the chair.

DELEGATES.

Dr. Jenks and Dr. Hutchinson from the Rhode Island Medical Society.

MEMBERS PROPOSED AND ELECTED.

Drs. G. M. Kimball, Thomas Hiland, Ellen A. Wallace, Concord; A. H. Taft, Manchester; J. B. Raynes, Bradford; George A. Allen, Bradford, Mass.; O. W. Goss, Lake Village; Ed. F. Houghton, Claremont; A. W. Blair, Orford; Bradford Allen, Nashua; W. W. Wilkins, Manchester; Charles A. Blake, State Workhouse, Mass.

THE COMING PHYSICIAN.

The president in his address, after reviewing briefly the past and present state of the profession, asked: Shall the practice of medicine sink to the level of a trade where every competitor supplements his skill as an artisan by all the tricks of cunning and diplomacy of which he is capable? Shall the body of the profession be broken up into fragmentary joints, each little segment calling itself a specialist, until the organs of the body are parcelled out as booty is divided among thieves? Shall the grand old column be broken up into detachments that shall ultimately destroy one another, because men honestly differ as to the means employed to subdue disease? Shall certain drugs and certain methods be considered Catholic and all else irregular and to be damned by bell, book, and candle? These are some of the dangers that have beset the onward progress of medicine in the past, and which are liable to retard its progress in the future. If we do not understand the wonderful worth and greatness of life our intellect will never be able to cope with the difficulties of our profession and enable us to withstand the temptations by which we are surrounded. Every created object is holy, as being God's workmanship. But as human life is the most marvelous and mysterious of all the emanations from the Deity it is entitled especially to reverential treatment. When the first Napoleon requested that lethal doses of opium should be given to those that were sick and would surely fall into the hands of an implacable enemy, the great surgeon replied: "It is my duty to save life not to destroy it."

The president spoke of the prevalence of abortion and its deleterious influence, physically and morally, upon society; and urged upon the medical profession their duty to exercise their utmost influence against the growing evil and to educate the people to a proper realization of the brink upon which they are standing. He then discussed the existing laws relating to coroner's inquests. You have in the coroner an officer armed practically with the utmost power of the law. He decides in the first place whether an inquest be necessary or not. Thus it is not difficult for him to close the door to all judicial investigation of a crime, and even to aid in the concealment of evidence by authorizing speedy burial. He may thus shield the guilty and injure public safety. On the other hand the opportunities for a man, prompted by malice or vindictiveness, or the desire for cheap notoriety, are enough to make us tremble. With full judicial powers of examination and commitment, with his chosen constable, selecting his own jury, with supreme control of the investigation, which, with the consent of part of his jury, he may make secret, with the selection of his medical witnesses, and the power to summon and hear, or omit and exclude whomsoever he will, uncontrolled by superior authority, and responsible, practically, to no one for his action, he may bring ruin upon a life, or forever cloud and embitter it, throwing suspicion on the character of the living and blackening the memory of the dead. In one word, he may make an inquest in the worst sense of the term, an inquisition. The sole purpose of the coroner's inquest is the detection of crime. When suspicion exists his functions are two-fold, one is to determine with certainty whether the death has resulted from natural causes or from violence; the other is, to determine, if it be found to be a case of violence, how that violence was caused and whether it constitutes a crime. One is a question of medical investigation; the other a question for legal determination. Let us try and have some law passed, relegating to each profession the functions belonging to them. Have medical examiners appointed in each county whose duty it shall be to take immediately possession of the body and ascertain the cause of death; if resulting from natural causes to turn it over to the undertaker; if from some unnatural cause, to report to the judicial officer whose duty it should be to take cognizance of crime.

The speaker then pointed out the duty of the physician to educate the community in sanitary science, the ventilation, heating, and drainage of dwellings and school-houses.

Therapeutics should be better understood. We are fast drifting into a refined dillettante style of prescribing and losing sight of the true value of a drug. Pharmaceutical chemists are filling our tables with fancy combinations, having a captivating nomenclature that would paralyze our ancestors were they to revisit us. Highly ornamental and extravagently written monographs, advertisements and recommendations of their preparations thrust upon us by agents, and making the principal portion of our mail, are crowding from our shelves books on therapeutics and materia medica. So many good old remedies have been lost sight of by these new styles that I am inclined to advise that we hold on to the few we have left a short time longer and let them produce their own chemical changes whilst wrestling with disease inside the body and not give up entirely to these new-fangled patent-back-action remedies that will hit most anything.

SCHOOL HYGIENE.

DR. D. M. CURRIER read an exhaustive essay upon this subject. He complimented the New Hampshire State Board of Health for the work they had accomplished in this direction. He suggested the ventilation of rural school-houses by constructing an incoming or cold air duct under the timbers of the floor, reaching from outside and opening directly upwards under the stove, and furnished with a valve to regulate the flow. Completely surround the stove by a galvanized iron case. Ventilation could be provided by placing a register in the chimney near the floor. The chimney should be large, and the smoke-pipe should pass through it to the top, thus creating a powerful ventilating draught.

REPORT ON OBSTETRICS.

DR. FRANK BLAISDELL closed his somewhat lengthy paper with the following summary: I have thus tried to indicate as well as I could in the limited time allowed a paper of this kind, the following: First, that the effects of modern civilization upon our child-bearing population is such, that our women are unfitted for the highest duties of motherhood, judged from a

physiological standpoint. Secondly, that there are in certain cases of confinement definite indications for the use of the forceps as a prophylactic agent in preventing results which often follow expectant treatment, and that the time of election for the physician to interfere, when interference is necessary, is preferably, the earliest time possible rather than to wait. Thirdly, that the use of anæsthetics in labor is too indiscriminate; they should not be used in every case of labor, but should be prescribed according to indications the same as any other remedy of like power, and that hæmorrhage is not the result of any particular anæsthetic agent, but the effect of the agent upon reflex uterine action. Fourthly, that there is considerable reason to believe that the utility of the membranes as dilators has been overrated. Fifthly, that the treatment of placenta prævia by Carr's method of pulling away the placenta entire, letting it precede the child, with rapid delivery of the child, has been eminently successful with those who have tried it, of saving both mother and child. And sixthly, that it is just as well to let the perineum alone in ordinary labor. I am aware that some of these views differ somewhat from the views advocated in our text books, but I have been led to them by considerable thought and a quite busy obstetric practice of nearly ten years. I have also seen many things in the writings of some of our best obstetricians that has strengthened me. None of you dislike meddlesome midwifery, as that term is generally understood, more than I, but I do believe in a mediatorial midwifery, a midwifery that will interfere to prevent suffering, that will assist nature when she falters, and will remove those conditions that will prevent her doing her perfect work and save a woman from the consequences that too often follow a too implicit faith in a power given to women in its perfectness and completeness by the Almighty, but misused, perverted, and oftentimes rendered ineffectual by the bad influences of our national life, and the follies of our progenitors; a midwifery that I believe would have led any one of you to have interfered and have saved Rachel to Jacob when she died in labor on the plain near Ephrath.

MEDICAL COMMON-SENSE.

DR. C. A. ALLEN closed with the following words: The time is coming when there will be no sects among educated physicians. The present war between the friends and opponents of the National Code but points the way. It will not be this year nor the next. It will be when the world has grown wiser and has learned to value at its true worth any creed that uses its name as an advertising medium only. It will be when elementary medicine is taught in our common schools; when common-sense shall reign in the minds of the people and they have learned that *pathy* does not make the doctor. It will be when our lawyers, our ministers and our teachers shall add a general knowledge of medicine to that of their regular calling. It will be when doctors depend upon their profession rather than to prop it up with statutory laws.

THEORY AND PRACTICE OF MEDICINE.

DR. J. F. BROWN discussed briefly the character and treatment of cholera infantum, typhoid fever, small pox, diphtheria. In the treatment of diphtheria he has always put in practice a mild caustic medication with antiseptic remedies at the outset. A mild solution of nitrate of silver every hour alternated with a soothing lotion, with tonic constitutional remedies. Some of the worst cases set in very insidiously, and before the family are aware of its severity, the whole system is saturated with the virus. With reference to the management of deep-seated, large and indolent ulcers, the difficulty is, after getting the sore into a granulating condition, to cause it to heal over without subjecting the ulcer to strapping and constant care on the part of the surgeon. Another plan is by the elastic stockings, which are invaluable in some cases.

In what is known as the oakum treatment of ulcers, the diseased surface must be brought into a healthy condition, and all effete matters removed by nitric acid or nitrate of silver with poultices. Then pick up oakum fine and soft, make a pad twice as large and proportionately thick with a fine piece of soft cloth laid over it and simple cerate dressing laid on the ulcer and the pad placed over it with oakum extending over the edges on all sides to make the pressure equable. Then bandage nicely.

I have adopted a method for the prevention of pitting of the face in small pox which I obtained from an old number of Braithwaite's Retrospect. I have modified it to some extent. What is desired is to stop ulceration before it has gone through the true skin. Insert a strong solution of nitrate of silver, about twenty grains to the fluid ounce into each pock. The manner of doing it is to prick the pustule with a lancet and press out the pus or serum, then put in the nitrate of silver solution on the point of the lancet. The large pocks immediately are less inflamed and less painful. The small ones scab over and fall off in a few days, leaving the face smooth.

REPORT ON SURGERY.

DR. C. B. HAMMOND read a lengthy article upon antiseptics. The ease with which bichloride of mercury is prepared, and its freedom from odor, makes it one of the most agreeable antiseptics. In the amputation of fingers, especially, it is rare to fail of obtaining good results by the following method. Having checked all oozing and bleeding, unite the flaps with carbolic catgut sutures, and place over the edges of the flaps a small piece of oiled silk. Over this, place a thick layer of borated absorbent cotton which has previously been wrung out in a solution of bichloride of mercury of the strength of 1-3000, taking care that the cotton shall come well down on the healthy skin. Over this, place another layer of dry, borated cotton and a piece of absorbent lint and a bandage. Remove this dressing in from five days to a week, and substitute a similar one for about the same length of time. I have been accustomed to use bichloride of mercury in the strength of 1-3000 as a post-partum vaginal douche, and find that even at this strength it may produce bad results; at least, I have seen a troublesome diarrhœa occur, which ceased upon discontinuing the injection. There is danger in its use for irrigating large wounded surfaces at the strength of 1-2000, and for any irrigation, that strength is sufficient.

The use of glycerine in dressings was discussed, and also the use of muriate of cocaine as an anæsthetic.

A case of recovery after herniotomy, performed for the relief of a strangulated femoral hernia, was reported, remarkable for the time that elapsed from the first symptoms to the date of operation, which was eighty-six hours.

FASHIONABLE FOLLIES.

Dr. M. H. Felt made an onslaught upon numerous novelties in medicinal preparations, speculative theories, and fashionable specialists.

TYPHOID FEVER.

Dr. I. H. Adams presented a short paper upon this subject, discussing the diverse opinions as to its origin.

NERVE WEAKNESS.

Dr. H. C. Holbrook spoke of functional nervous disorders, briefly tracing their sources, progress, and symptoms. In the treatment of chronic neuropathic disorders, the general condition of health and nutrition must not be overlooked. Tonics are indicated in most cases, and of these, a bitter, like salicin or cinchonidia, in combination with strychnia, diluted phosphoric acid and the chloride of iron, gives the best result in the largest number of cases. Elixir of phosphate of iron, quinine, and strychnia is a powerful tonic, but in some cases cannot be borne, except in small doses. Sedatives should not be used too freely. Opium and chloral hydrate should be very sparingly tried, for these patients form the opium and chloral habit most readily. A nerve, made over-irritable by anæmia, can be quieted more effectually by enriching the blood than by giving a drug. Sedatives should never be used to the exclusion of tonic remedies. Bromides may be given for a long time without injurious effect, combined with some powerful reconstituent. The use of drugs which directly affect the nervous system was briefly discussed, and also general electrization and dry cupping.

AN IMPROVED METHOD OF MEASURING THE CHEST.

Dr. Wilkins. The improvement consists, first, in a double tape-measure, or, in other words, a measure that commences to enumerate from a common centre; second, the establishment of a middle, anterior perpendicular line of the chest, from which to take comparative measurements of the two sides. The method was described at length, and its advantages pointed out.

The death of Dr. C. F. Bonney, of Manchester, was reported by Dr. Howe, and the death of Dr. Joseph H. Smith, of Dover, by Dr. Hill.

Reports of delegates to other societies, and to the Dartmouth Medical College were received.

A Committee was appointed to consider the preparation of a history of the Society, Dr. I. A. Watson, Chairman.

The following officers were elected: President, Prof. C. P. Frost, of Hanover; Vice-President, Dr. S. W. Roberts, of Wakefield; Treasurer, Dr. D. S. Adams, of Manchester; Secretary, Dr. G. P. Conn, of Concord; Anniversary Chairman, Dr. M. H. Felt, of Hillsborough Bridge.

Recent Literature.

Transactions of the Obstetrical Society of London. Vol. XXVII, for the year 1885. London: Longmans, Green & Co. 1886.

This volume of Transactions contains, as usual, a large amount of valuable material which has appeared in the society reports, as given from time to time in the current medical literature, but which becomes additionally available when collected in book form. Some of the articles have been noticed in the half-yearly report on the Progress in Gynæcology. The most noteworthy contributions in the present volume will be briefly referred to.

Dr. Duncan's paper "On Extirpation of the Entire Uterus," after giving the details of two vaginal extirpations, urges very strongly the claims of supra-vaginal amputation, on the grounds of its being the safer operation, and that the ultimate results are better. He supports his position ably by statistics.

Dr. John Williams's paper on "The Circulation in the Uterus" is of special importance, on account of its bearing on the question of the interference with the circulation caused by flexion, a fact which he denies. An abstract of this paper was given in the Journal a few months ago.

Two papers by J. Matthews Duncan, one on "Ulceration," the other on "Hypertrophy of Lupus of the Female Generative Organs," both illustrated by plates are important contributions to our knowledge of these conditions.

Dr. Williams has a second paper on "Serous Perimetritis," and gives the histories of three cases. A very interesting article is one by Dr. W. O. Priestly, describing some of the lying-in hospitals in the north of Europe, and referring to the advantages of the antiseptic system in obstetric practice. He gives very fully the methods employed at the Maternity Hospitals at Copenhagen, Helsingfors, and one at St. Petersburg.

The last of the more important papers is one by Dr. Herman "On the Suppuration and Discharge into Mucous Cavities of Dermoid Cysts of the Pelvis." He discusses the course of such cases, the prognosis and treatment, and gives short abstracts of numerous illustrative cases.

Besides these more lengthy communications, there are a large number of interesting shorter articles. The present volume compares very favorably with those of former years.

— Dr. Govan, of Rockland County, stated at the New York Medical Association that he had used aniline oil for the purpose of producing local anæsthesia when laying open felons and performing other minor operations. There was absolutely no pain, even when cutting down to the bone, when the finger had first been dipped for a short time in the oil.

— In Vienna it is customary to give medical men their fees at the end of the attendance, so that the payment is understood to be equivalent to a notice that no more visits are to be paid without further request. A legal case recently turned on this point. A tailor having a child sick with some febrile complaint, sent for a physician, who was unable at that stage, to make a positive diagnosis. He was tendered his fee, and in accordance with the implied understanding, made no further visits. The child was later discovered to have small-pox. On judicial inquiry the physician was acquitted, and the father punished for concealing the character of the disease, and for taking work into his house while the child was sick. We are moved to the reflection, if this method of dismissal was in vogue in this country, how many years, in some cases, the physician would have to remain in attendance.

Medical and Surgical Journal.

THURSDAY, JULY 8, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

MODERN VIEWS AS TO FUNCTIONS OF THE LIVER.

THE ancients possessed very vague notions as to the functions of the liver. Hippocrates classed bile with atrabile among the four humors, an excess of which engendered disease, and taught the necessity of purgatives to eliminate bile. Galen believed the bile to be excrementitious, and that its ready and constant elimination was demanded in the interest of good health. But Galen had other notions as to the hepatic functions. To him, the liver was the centre of animal heat and of the circulation, and the blood-making organ *par excellence*. It is singular that modern experimentation should have gone far to confirm these speculative views of Galen as to the influence of the liver in both thermogenesis and hæmatopoiesis. To this we shall allude in another number.

To the ancients, bile was purely excrementitious. In the seventeenth and eighteenth centuries, it became known that it was recrementitious also, and the heretofore prevalent notion that this fluid served only a depuratory purpose in the economy, came to be hotly contested. Bertholin, Aselli, and Haller assigned to it an important rôle in promoting digestion. The discovery of the lacteal vessels by Aselli in 1622, and of the thoracic duct by Prequet, in 1647, opened up to the comprehension of physiologists a new way by which chyle might be conveyed from the bowel into the blood quite independently of the portal vein and the liver, and the latter at once fell from its high position as a blood-former to which Galen had raised it.

Haller, from anatomical considerations, reasoned that bile was an essential adjuvant to the digestive process,[1] as the chyme underwent admixture with the fluid before its final elaboration. This view, however, at the beginning of this century, was almost entirely speculative, and in practice, bile was treated in accordance with Galen's notion, as being both noxious and excrementitious. Abernethy was, amongst English physicians, the most conspicuous advocate of the condition called *biliousness*, and was the apostle of blue pill and black draught. In this country, Rush first promulgated the notions of biliousness which have since so widely prevailed.[2] There was a classic train of symptoms: headache, furred tongue, loss of appetite, and nausea — if vomiting occurred, bile was present in the vomited matters — the stools were generally dark and offensive, the urine was loaded with lithates. The clinical observer was struck by the marked relief which, in these cases, always followed the exhibition of purgatives which evacuated bile.

The therapeutics of that period, though indefinite in theory, were quite simple in practice. The word *biliousness*, so much in use, was a convenient one for a time when the knowledge of the digestive, and especially of the hepatic functions, was so meagre and so obscure. It covered a vast amount of ignorance of matters connected with derangements of those functions, while apparently explaining everything, and the pathological state having been affirmed, the "cleansing calomel" and the black draught followed, as a matter of course. It was considered good practice also to precede the mercurial by small doses of tartar emetic, to provoke the liver to empty itself of all the bile that it contained. Nor were practitioners of that day unmindful of the necessity of a spare diet in biliousness, and their treatment (despite the incompleteness of their theory) was often attended by beneficial results; only a "bilious" condition was often diagnosticated and treated where serious organic disease underlay the morbid phenomena.

We have to come down to the century in which we live to find recorded any precise physiological experiments made to ascertain the office of the liver, and especially of the bile. These date from the ligation by Blundell, Brodie, and others, of the common bile duct. It was noticed that animals speedily died after this experiment, killed, as was then supposed, by bile-poisoning. Schwann, however, showed that the establishment of biliary fistulæ in animals, in which the bile was all lost — not retained in the system — was also followed by death, the fatal issue being preceded by rapid emaciation; this proved that the bile had some other use besides being simply excrementitious.

Still later in this century, Bidder and Schmidt performed some notable experiments of the same kind on dogs; they found that the animal lost daily, by the fistula, bile to the amount of one-fiftieth of its weight; if, however, the daily rations of the animal were increased proportionally to this loss, life could be indefinitely prolonged. These experiments, confirmed by Kolliker and Muller, go to show that bile is not indispensable to digestion, but its continuous waste by a fistula is incompatible with life without compensation for this loss by a copious alimentation.[3]

The speedy death of the animals in which the common bile duct was tied does not seem to be due so much to the toxic nature of the biliary ingredients retained, as to exhaustion consequent on the imperfect assimilation of food; many pathological facts bear out

[1] Haller's Elementa Phys. (quoted by Longet).

[2] Bartholow. Pepper's Syst. of Med., Vol. II, p. 965.

[3] Longet's Traite de Phys., Vol. I, p. 288.

this inference. Thus Dr. Budd mentions several cases "in which the passage of bile into the intestines was entirely prevented by complete closure of the ductus communis, and in which, nevertheless, life was prolonged for many months. In one of them, the jaundice first occurred in a woman four months pregnant, who, nevertheless, bore a living child at full period, and suckled it up to the time of her death, which happened when the child was three months old." [4] The greater part of the elements of bile are substances which, when re-absorbed, can be appropriated to nutrient uses in the economy: such are the mucus, the chloride of sodium, the phosphate of lime, the sulphur, the phosphate, carbonate and lactate of soda; the resinoid principles, the coloring matters, and the cholesterine are truly excrementitious.[5]

As for the emaciation which follows the establishment of a biliary fistula, this is a fact that has been determined by many experimenters, and while there is much obscurity on this point, there seems to be good evidence that bile aids the saponification and absorption of fats. It has been proved that jaundiced patients digest fats incompletely, and the same is true, according to Bidder's and Schmidt's very accurate experiments with dogs with biliary fistula; only one-fifth or one-seventh the usual quantity of fat is absorbed. Brodie, Mayo, Tiedmann and Gruelin, Leuret, and Lassaigne, have found the chyle in the lacteal vessels nearly transparent and free from fat under such conditions.[6]

Light may be obtained respecting the offices of the bile when we come to study the sources of that fluid, but this consideration must be reserved for another number.

MEDICAL EDUCATION IN CHINA.

The difficulties in the way of educating the natives of China to any satisfactory degree in the knowledge of scientific medicine are very great, involving, first, the dispossession of their minds of the crudities and absurdities of their traditions on such matters, the necessity of instructing them in one of the European languages in which there is a medical literature, and the securing of clinical opportunities, to say nothing of the task of cultivating in them a truly scientific spirit of inquiry. So far has this been true that even the assistants in the European hospitals in China have never been able to acquire more than a certain manual dexterity. Dr. Myers, however, at the David Manson Memorial Hospital of Takow, Formosa, has had the honor to be the founder of what promises to be a successful as well as most important work in this direction. The *Hongkong Telegraph*, under date of May 20, gives a most interesting account of it. Two young Chinamen have completed, with marked credit to themselves, the first half of a full medical course at this hospital.

[6] Ib., Vol. II, p. 311.

The regulations under which it is proposed to grant a certificate of competency, and which we think might in some respects be advantageously adopted by some of the American medical schools are these:—

No candidate will be accepted who is not thoroughly able to read and understand English.

The first examination, to be held not earlier than at the end of the candidate's second year of study, to be on anatomy, physiology, inorganic chemistry, and elementary surgery.

Examiners to be independent medical men at either Hongkong or Shanghai, who are to have the sole conduct of the examination of the aforesaid subjects, and whose decision is to be final.

On passing the first professional examination, the candidate is to study for a further period of two years, at the end of which time he may present himself for examination before another independent Board of Examiners, at either Hongkong or Shanghai, when he will be examined on practice of medicine, midwifery, clinical medicine, clinical surgery, including use of instruments medical and surgical, and bandaging, with materia medica, and pharmacy. On passing this, the examiners will sign the final certificate of competency, which will then be handed over to him.

No candidate can be admitted to the first examination unless he produce to the examiners a certificate, duly authenticated, that he has studied for the space of two years, under a legally qualified medical man, all the subjects he professes, at a hospital or medical school to be approved by the Board of Examiners, and no candidate can offer himself for examination at the final unless he can produce certificates of having studied the professed subjects during the required period.

The certificate of competency, drawn up in English, Chinese, or Latin, is divided into two parts, the examiners for the respective divisions signing immediately under their certificates, the whole confirmed by the Surgeon and Instructor of the D.M.M. hospital, and further authenticated by the signatures of the Hospital Committee. To prevent fraud, the photograph of the holder, stamped with the die of the hospital, is affixed to the diploma, and sundry other precautions are taken.

About two and a half years ago, two promising students from the Central School, Hongkong, named respectively Chan Chun Kai and Li Tsun Fun, volunteered to go to Formosa, and study for the required periods, the hospital offering to find them board and lodging, together with instruction.

They have lately been presented for their first examination before a Board of Examiners composed of surgeons of the British Army and Navy and colonial medical officers with one native who is well educated in chemistry. The requirement of the Hospital that the Board be as cosmopolitan as possible seems to have been complied with.

The *Telegraph* says that it was as formidable a board as could possibly be got together outside of the

United Kingdom, and indeed, looking at the eminence of its members, no less from an official than professional standpoint, it is quite open to question whether a stronger or more authoritative tribunal could be obtained, even in England.

The papers which they submitted in anatomy, chemistry, surgery and physiology, occupying three or four hours apiece, are before us, and would be no light test to the students in the best of our own schools. When we consider that the test was framed and applied by men of such character, having had no connection with the instruction of the students, and in a city remote from where the instruction was given, and that the two candidates obtained in the average of the subjects 72.6 and 70.5 per cent., respectively, we are forced to the conclusion that somebody has been doing pretty good work in the beginning of medical education in China, and are led to the reflection that could a board equally independent of the teaching bodies, and as strict in its requirements, be entrusted with the authority to grant diplomas in medicine in this country, there would be considerable falling off in the number of diplomas which the recurring seasons bring forth.

MEDICAL NOTES.

— The New York Legislature has passed a law for the regulation and control of the practice of veterinary medicine. The law requires the registration of all practitioners, with the evidence of proper qualification afforded by a diploma from some legally incorporated college, or a certificate from an incorporated veterinary society. New York is the first and only State in the Union to recognize and protect this profession, as it was the first to establish veterinary schools, and to organize a State veterinary society.

— The Ohio State Medical Society, at its forty-first annual session at Akron, June 2, 3, 4, 1886, elected the following officers: President, Thomas MacEbright, of Akron; First Vice-president, J. M. Weaver, of Dayton; Second Vice-president, W. S. Battles, of Shreve; Third Vice-president, X. C. Scott, of Cleveland; Fourth Vice-president, Jesse Snodgrass, of Kenton; Secretary, G. A. Collamore, of Toledo; Assistant Secretary, E. C. Bush, of Zanesville; Treasurer, T. W. Jones, of Columbus. The next meeting will be held in Toledo.

— The Kentucky State Medical Society, at its thirty-first annual meeting, held at Winchester, June 23, 24, 25, 1886, elected the following officers: President, M. R. Watkins, of Louisville; Senior Vice-president, J. M. Harwood, of Shelbyville; Junior Vice-president, J. H. McKinley, of Winchester; Permanent Secretary, J. Steel Bailey, of Stanford; Assistant Secretary, T. C. Simpson, of Bardstown; Treasurer, Edward Alcorn, of Hustonville; Chairman Committee of Arrangements, J. C. Brooks, of Paducah. Next place of meeting, Paducah, the third Wednesday in June, 1886.

— *Il Morgagni* (May 29) mentions the following case, recorded by Polyakoff in the *Meditsinskæ Obezpénye*, No. 10, 1885. A robust peasant, aged twenty-seven, of Syarai, Russia, after nine years' married life, became pregnant for the seventh time in June. In the latter period of the pregnancy, the abdomen assumed vast proportions, and on the 1st of March, the woman gave birth to five female fœtuses at short intervals, three presented by the occiput, two by the feet. Each had a sac with separate amnion, but the chorion was common to all. The first fœtus was deformed and still-born; the others lived some minutes after birth. The single placenta weighed a pound and a half, and the umbilical cords were attached to its extremity. Four of the fœtuses were well formed; but the first born was microcephalic, and had not the full number of fingers or toes. The umbilical cord attached to this fœtus had an artery and a vein, but each of the others had three vessels.— *Lancet.*

BOSTON.

— The first class in veterinary medicine was graduated from Harvard University, June 30. It consisted of five members.

— The jury disagreed in the second trial of Stogdale vs. Baker, in which our readers will remember a patient of the Free Hospital for Women brought suit against Dr. W. H. Baker for malpractice, in performing an operation upon her, as she alleged, without her knowledge or consent, in that hospital. A similar suit against the Hospital some months ago, was decided against the plaintiff.

NEW YORK.

— Dr. Joseph Wiener, a well-known German physician, who has practised for many years in New York, has presented to the Park Commissioners a colossal bust of Washington Irving, executed by Beer, of Paris. It will be placed on a pedestal eight feet high, in Central Park.

— A very large rhinoceros, which was recently landed from Europe and taken to the Central Park menagerie, died of pneumonia one week after its arrival there. At the autopsy, which was conducted by Dr. Liautard, it was found that the carcass weighed a little over seven thousand pounds, and the skin alone, eight hundred pounds, requiring eight men to lift it. The thickness of the hide varied from one and a half to two and a half inches. The pneumonic consolidation involved the upper portion of the right lung, and the left was unaffected.

— A warning to amateur doctors, as well as to druggists, is afforded by a case just decided. A German suffering from malaria was informed by a friend that hydrate of chloral would cure his trouble, and accordingly, he purchased some and took a considerable quantity (the dose is not given in the report). He was afterwards ill for six weeks, and claiming that it was caused by the chloral, and attributable to the carelessness of the druggist of whom he purchased it, on the ground that the latter should have warned him

respecting the powerful character of the medicine, he sued the druggist for $2,000 damages. At the trial, it was urged, on behalf of the defendant, that the plaintiff informed him that he knew all about the drug, but the jury rendered a verdict awarding the latter $200 damages.

Miscellany.

THE EFFECT OF BITTERS ON DIGESTION.

Dr. Cheltsoff, Chief of Professor Botkin's clinic, according to the *Lancet* (May 15), thinks that extracts of the so-called "pure bitters," which are usually prescribed with the view of stimulating the secretion of gastric juice and of aiding digestion, so far from having any beneficial effect of that kind, are absolutely injurious, inasmuch as they retard the digestive functions. He has made a series of experiments with extracts of aurantium, gentian, trifolium, absinthium, calumba, cascarilla and quassia, on (1) gastric digestion and the secretion of gastric juice; (2) pancreatic digestion and the secretion of pancreatic juice; (3) the secretion of bile; (4) fermentation; and (5) nitrogenous metamorphosis. The conclusions at which he arrived were that bitter extracts, even in small doses, interfere with artificial gastric digestion, and also with the gastric digestion of animals, but not to so great an extent. Large doses of bitter extracts diminish the secretion of gastric juice, though small doses effect a slight and transitory increase of it, the digestive power of the fluid being, however, in all cases diminished. Bitter extracts have no effect on the secretion of pancreatic fluid, but they, nevertheless, retard hypogastric digestion. The action of bitter extracts on the secretion of bile is various; extract of absinthium, extract of trifolium, and large doses of extract of cetrarin slightly increase it, usually at least, but not invariably; while extract of quassia, extract of calumba, and small doses of extract of cetrarin, have no effect at all. Bitter extracts have no antifermentative effect, and do not hinder suppuration. Lastly, assimilation of nitrogenous substances is diminished by the use of these extracts.

COMMUNICATIONS FROM THE DIPHTHERIA WARDS OF THE CHARITÉ.

Henoch's report on diphtheria, as observed in the wards of the Royal Charité, at Berlin (*Charité Annalen*, Vol. X, p. 490), embodies much interesting and valuable material. Its conclusions are thus summarized in the *Therapeutic Gazette* for June.

Diphtheria increases, as appears from the publications of the bureau of statistics, yearly in Berlin, both regarding frequency and malignancy. The same observations could be made at the Charité. From the years 1876–1883, the number of diphtheria patients increased enormously, namely, from twenty-six to one hundred and eighty-three. About two-thirds of all cases belonged to the period between the second and sixth year of life. The mortality rate is most unfavorable in the first three years of life.

Of three hundred and nineteen cases observed, two hundred and eight died (an enormous percentage). It must be taken into consideration, however, that, aside from a grave epidemic nature and the naturally unfavorable conditions of a large old hospital, only genuine cases of diphtheria are included in the above statement.

Of the three hundred and nineteen cases, one hundred and seventy-four took their course without exceeding the region of the pharynx; of these, ninety-five were cured and seventy-nine died. This great number of cases with a lethal exit, which did not terminate under symptoms of croup, confirm the frequently-noted fact that the very gravest septic forms of diphtheria show no tendency to extend downward, not even when they attain a duration of seven days and more. One hundred and forty-five cases assumed a croupous nature, and were all operated upon, with the exception of seven cases. These seven patients perished, while of the one hundred and thirty-eight operations, only sixteen (about eleven and a half per cent.) were successful. These figures show that in spite of all the dangers which lie in the diphtheritic infection itself, the termination in croup slays the greatest number of victims. Henoch regards the combination of grave septic symptoms with those of croup as the only tenable contraindication to the operation of tracheotomy. Among the causes of death after tracheotomy, we find, besides affections of the respiratory organs mentioned, diphtheritic collapse, erysipelas, and (in three instances), convulsions appearing twelve to forty-eight hours after the operation; for these no valid reason could be assigned, even after the autopsy. Otitis media was observed only in three cases; rhinitis diphtheriticus, however, in very many instances, even in those which terminated in a cure.

The conjunctiva palpebrarum was but rarely, and only in grave cases, affected. Erythemata occurred in three cases, scarlet fever in many, nephritis in some. When, in presence of nephritis, symptoms of cardiac weakness set in, injections of camphor, ether, and strychnine were employed, to which, in some instances, Henoch attributed the recovery. In diphtheritic paralysis, hypodermic injections of one to four mg. of strychnine constituted Henoch's routine treatment. Of prolonged diphtheritis, Henoch noted also a few cases, one of which lasted over two months up to its recovery.

In conclusion, Henoch declines to admit that any of the vaunted specific measures can be regarded as reliable.

SEWAGE FARMING IN ENGLAND.

On June 3d, inst., Dr. Alfred Carpenter delivered an address to the Croydon Farmers' Club, which was of much more than local interest. The sewage of Croydon flows by gravitation to the two sewage farms of Beddington and Norwood. The Beddington farm of six hundred acres disposes of the sewage of 66,000 persons; it has been in operation for more than twenty years; it has never given rise to any nuisance or any disease in the neighborhood; the land has risen from £1 to £9 per acre in value, and is still as capable of doing its work as it was when it was first used. This is a most important tribute to the value of sewage irrigation, and proves that the oft-repeated statement that land soon gets "sick" of sewage is, at any rate, not universally true. The *Lancet* says: "The whole address was full of matter for thought, and should be reprinted as one of the most valuable of the recent contributions to the solution of the hardest of sanitary problems."

"Some years ago we reported on the two Croydon farms, and we gather from the above address that they have undergone no important alteration since that time. There is a great natural fall to help the irrigation, and the sewage can easily be carried to the growing crop of rye-grass before putrefaction has advanced. This, Dr. Carpenter claims, is a great advantage, as he has satisfied himself by experiments that rye-grass is almost carnivorous in its power of assimilating crude sewage. We are inclined to agree in this view, although the evidence adduced is scarcely conclusive. The sewage flows, or did flow at the time of our inspection, over the soil, and not through it, the system being correctly described as surface, as distinguished from downward, filtration. It is wonderful how effective, when properly managed, such filtration is in removing organic matter from sewage, and the long-continued success of the Croydon experiment seems to indicate that it is in some cases, if not in all, the best mode of working. The soil in the Norwood farm is stiff clay, and would be ill-adapted for underdrainage, whereas, even in wet weather, a satisfactory effluent can be obtained from the surface.

"Dr. Carpenter insists with great sense on the necessity of making the sewage irrigation intermittent. There is no doubt that the occasional failure of what is certainly, when practicable, the best method of sewage disposal has often been due to the neglect of this precaution. Even Italian rye-grass, which, as the Rugby Commission long ago proved, is the only crop suited for the continuous assimilation of sewage, requires some time for the digestion of its food; and it is, above all, desirable that a week or more should elapse between the last application of sewage and the cutting of the grass. The economical disposal of the crops is a distinct and almost equally important question. The grass should be cut frequently, before flowering, and the suggestion that a stock and dairy farm should be associated with the sewage farm is well worthy of consideration; it would probably pay, in a good many places."

SOME CERTAINTIES IN THE THERAPEUTICS OF EPILEPSY.

DR. C. L. DANA has written a paper with the above title, which is published in a recent number of the *New York Medical Journal*. His conclusions are summarized in the following statements: —

I. Diet, exercise and proper hygienic treatment rank above all other single therapeutic measures.

II. The bromides take the second rank in the treatment of epilepsy.

All bromides act alike in this disease. If one does not cure another will not. Occasionally changing and mixing reduces the attacks for a time, and benefits the stomach.

III. The best bromides are those of potassium, sodium, ammonium, and hydrogen (hydrobromic acid); possibly we may add nickel.

IV. Bromides may be given in daily doses of ʒj, increased gradually until the attacks are suppressed, or the dose reaches ʒiv to ʒj daily. Few patients can tolerate more than this latter dose. Thorough bromidization should be always tried, if necessary to stop fits, and it may be occasionally repeated. But bromidization is sometimes injurious, even making the disease worse, and it must always be employed with caution.

V. When the fits are suppressed, the bromides should be carefully reduced, but never entirely stopped for at least two years after the last fit.

VI. In most cases, and especially in nocturnal epilepsy, an extra large dose of bromide should be given at night.

VII. It is very important that bromides should be chemically pure, that their use should be continued a very long time, and that their depressing effects should be offset by tonics and all possible roborant measures.

VIII. The best non-specific adjuvants (drugs) to the bromides are potassium iodide (in syphilitic epilepsy), potassium bicarbonate (in lithæmic and rheumatic states), carbonate of ammonium, the hypophosphites, arsenic, iron and quinine.

IX. The other chief adjuvants to the bromides are diet, exercise, a regular life, hydrotherapy, counter-irritation on the neck, and, in the line of drugs, zinc, belladonna, strychnine, valerian and the nitrites. Combinations of bromides with the other drugs mentioned will lessen attacks when bromides alone will not.

X. The best substitutes for the bromides, when these do no good or do harm, are belladonna, zinc, strychnine, glonoin, borax and alteratives.

For nocturnal epilepsy, increase the dose of bromide at night, and add chloral or digitalis. Give also, if needed, strychnine. Raising the head of the bed or making the patient sleep in a chair at night are measures to be tried.

For the status epilepticus give large enemata of chloral, and use emetics and purges. Venesection is often efficacious, morphine is dangerous, chloroform is only palliative, and nitrite of amyl is of little value.

THE CHARACTER OF INORGANIC CARDIAC MURMURS.

SIR JAMES SAWYER, M.D., writes in the *Birmingham Medical Review* for April, regarding the statement that Dr. G. W. Balfour was the first to draw attention to the greater frequency of the inorganic murmur of chlorosis to the left of the sternum, saying that the fact was generally accepted by clinical teachers sixteen years ago. This writer is unable to accept Dr. Balfour's well-known view as to the mitral origin of the systolic murmur of spanæmia, his opinion being that this inorganic cardiac murmur has its position of origin at the orifices of the aorta and pulmonary artery; that it is conducted along both the aorta and pulmonary artery; and that it can be traced more distinctly in the direction of the pulmonary artery than along the line of the aorta, because the pulmonary artery is larger than the aorta in circumference, and because it is nearer than that vessel to the anterior surface of the chest. He is quite satisfied that the auscultatory characteristics of the cardiac murmur of spanæmia, as to position, time, and propagation, are sufficient for its easy and certain clinical recognition.

In most cases of spanæmia, a cardiac murmur is audible. This murmur is not "organic"; it is independent of organic changes in the heart. It is not "dynamic"; it is independent of functional perversion of the cardiac action. This murmur is often heard in anæmic girls, and it has been distinguished by the names of anæmic and chlorotic murmur. In his expe-

rience, it is always basic in site. It is never heard over the cardiac apex. It is always systolic in rhythm, and systolic only. It can be traced upwards and to the right along the aorta, and upwards and to the left along the pulmonary artery, but it is more distinctly propagated along the pulmonary artery than in any other direction. It is not safe to rely upon the quality of this murmur, as some observers have seemed inclined to do. While an anæmic murmur is usually soft and blowing in quality, it is certainly not always so. When this murmur is audible, the cardiac second sound, as heard at the base of the heart, is often preternaturally clear. It is unduly clear without being accentuated, and this abnormal distinctness pertains to both its aortic and its pulmonary valvular elements. The cardiac murmur of anæmia diminishes as the patient's condition improves, and disappears with complete convalescence. It is generally better heard in the erect than in the recumbent posture. There are two associated auscultatory signs of spanæmia: namely, the well-known hum in the neck (the continuous venous murmur known at the "*bruit de diable*.") and a less constant murmur, which is softly blowing and systolic, audible over the larger arteries.

REPORTED MORTALITY FOR THE WEEK ENDING JUNE 26, 1886.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from				
				Infectious Diseases.	Consumption.	Diarrhœal Diseases.	Whoopi'g Cough.	Diph. and Croup.

Deaths reported 1,803: under five years of age 813: principal infectious diseases (small-pox, measles, diphtheria, and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 522, consumption 284, diarrhœal diseases 239, lung diseases 146, diphtheria and croup 93, whooping-cough 30, malarial fever 23, measles 22, scarlet fever 20, erysipelas 12, cerebro-spinal meningitis seven, typhoid fever six, puerperal fever one. From malarial fever, New Orleans 10, New York seven, Baltimore three, Brooklyn two, District of Columbia one. From measles, New York nine, Baltimore eight, Charleston three, Brooklyn and Pittsburgh one each. From scarlet fever, New York six, Brooklyn and Pittsburgh five each, Boston two, Worcester and Holyoke one each. From erysipelas, New York six, Brooklyn, Baltimore, Providence, Charleston and Cambridge one each. From cerebro-spinal meningitis, New York four, New Orleans, Springfield and Fitchburg one each. From typhoid fever, Baltimore, District of Columbia, Pittsburgh, Charleston, Lowell and Lawrence one each.

In 20 cities and greater towns of Massachusetts, with a population of 976,894 (population of the State 1,941,465), the total death-rate for the week was 18.02 against 15.49 and 15.26 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending June 12th the death-rate was 17.4. Deaths reported 3,037: infants under one year of age 691; acute diseases of the respiratory organs (London) 216; measles 89, whooping-cough 60, diarrhœa 47, fever 28, diphtheria 18.

The death-rates ranged from 9.0 in Brighton to 34.5 in Portsmouth; Birkenhead 13.1; Birmingham 15.1; Bradford 19.7; Hull 18.8; Leeds 21.5; Leicester 15.3; Liverpool 19.0; London 16.1; Manchester 24.8; Nottingham 15.6; Sheffield 15.6; Sunderland 18.8.

In Edinburgh 22.5; Glasgow 23.0; Dublin 20.8.

In the 28 greater towns of England and Wales with an estimated population of 9,093,817, for the week ending June 19th, the death-rate was 16.8. Deaths reported 2,927; infants under one year of age, 689; acute diseases of the respiratory organs (London) 184, measles 89, diarrhœa 59, whooping-cough 60, scarlet fever 35, fever 29, diphtheria 21.

The death-rates ranged from 10.9 in Birkenhead to 39.6 in Preston; Birmingham 17.8; Blackburn 26.8; Bradford 18.5; Hull 15.0; Leeds 17.5; Leicester 16.1; Liverpool 18.2; London 14.9; Manchester 21.3; Newcastle-on-Tyne 21.2; Sheffield 16.3.

In Edinburgh 20.9; Glasgow 24.5; Dublin 22.9.

The meteorological record for week ending June 26, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 26, 1886, TO JULY 2, 1886.

McPARLIN, THOS. A., colonel and surgeon. Granted leave of absence for two months, with permission to apply for an extension of one month. S. O. 146, A. G. O., June 25, 1886.

MAGENDER, D. L., lieutenant colonel and surgeon. Granted leave of absence for two months, to take effect on or about July 1, 1886. S. O. 146, A. G. O., June 25, 1886.

PAGE, CHAS., lieutentant colonel and surgeon. Leave of absence extended ten days. S. O. 146, A. G. O., June 25, 1886.

PROMOTIONS.

BROWN, JOS. B., lieutenant colonel and surgeon. To be surgeon with the rank of colonel, Jan. 24, 1886.

HEGER, ANTHONY, major and surgeon. To be surgeon with the rank of lieutenant colonel, Jan. 24, 1886. Circular, A.G.O., June 28, 1886.

VICKERY, RICHARD S., major and surgeon. Assigned to duty as surgeon in charge of Army and Navy General Hospital at Hot Springs, Ark. S. O. 50, A. G. O., June 30, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING JULY 3, 1886.

GREEN, E. H., passed assistant surgeon. Ordered to Naval Laboratory at Brooklyn, temporary duty.

BROWN, J. M., Medical Director. Member of Retiring and Examining Board.

OGDEN, F. N., assistant surgeon. Ordered to "Juniata."

SIEGFRIED, C. A., surgeon. Three months leave abroad.

HALL, J. H. H., passed assistant surgeon. Detached from Museum of Hygiene, ordered to Naval Hospital, at Brooklyn.

WENTWORTH, A. R., assistant surgeon. Detached from "St. Louis," and ordered to "Brooklyn."

DECKER, CORBIN J., assistant surgeon. Ordered to "St. Louis."

BERRYHILL, T. O., assistant surgeon. Ordered to Museum of Hygiene.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE HOSPITAL SERVICE FOR THE TWO WEEKS ENDING JUNE 26, 1886.

SAWTELLE, H. W., surgeon To proceed to Wilmington, Cal., on special duty. June 22, 1886.

WHEELER, W. H, passed assistant surgeon. Granted leave of absence for thirty days, June 23, 1886.

WILLIAMS, L. L., assistant surgeon. To proceed to Buffalo, N Y., for temporary duty, June 24, 1886.

NORMAN, SEATON, assistant surgeon. To proceed to Cleveland, Ohio, for temporary duty, June 26, 1886.

Original Articles.

A CASE OF "ULCERATIVE ENDOCARDITIS."[1]

BY GRACE WOLCOTT, M.D., OF BOSTON.

On the 17th of October, 1884, I was called to see Mrs. R. M., a woman forty years of age. She had been a tailoress until her marriage, six years before. She told me that three years previous to this visit she had rheumatism, for which she was treated about one year. She fancied that the remedies given her then increased the menstrual flow very much at first, and finally arrested it altogether. This so alarmed her that she refused to take any more medicine and had had no further treatment up to the time that I saw her, although she had suffered greatly with her heart in the mean time.

She was a slender woman rather over medium height. Her face was very pale, her lips bluish, cheeks sunken. She seemed very nervous and her voice was tremulous.

Her pulse was 108, very irregular in volume and rhythm, and frequently intermitted. The radial pulse was so weak that I could not count it accurately, and from this time I was obliged to take the pulse over the heart's apex.

Temperature and respiration were normal.

The bowels were constipated. The tongue was furred and the breath foul.

She complained of gaseous dyspepsia, and of pain over the apex, accompanied by dyspnœa and palpitation, after any physical exertion or mental excitement.

Physical examination showed the apex beat to be in the fifth interspace, three and one-half inches from mid-sternum, and the area of cardiac dulness to be somewhat increased.

At this examination the heart's pulsations were so weak and irregular that no diagnosis of the valvular condition was made.

The treatment was directed to the heart itself and the sluggish condition of the bowels, as I thought the dyspepsia was secondary. The bowels were unloaded by a simple laxative, and under the influence of the tincture of digitalis the number of pulsations was reduced from 108 to 80 per minute, the beat becoming stronger and more regular.

Auscultation then revealed a double mitral and a double aortic murmur.

The dose of digitalis was then reduced from gtt. x to gtt. iii, three times daily, and she was given a pill of cinchona, iron and gentian, and under this treatment she gradually improved. Two weeks from my first visit her pulse was 74 per minute and regular, the bowels moved daily, and she was able to go up and down stairs and to take long walks without discomfort.

She continued in this condition until November 26th, when after severe nervous excitement she came to my office suffering from palpitation, dyspnœa and dyspepsia, with a pulse which varied from 116 to 128 beats per minute. Digitalis was again administered, and soon all trouble subsided.

On January 12, 1885, I was again called to see her. She had taken a severe cold and had rheumatic pains with constipation, headache, anorexia and vomiting. The pulse was 120, the apex beat very feeble. Her face was extremely pale. She was put to bed and the tincture of digitalis was again given in gtt. x doses, and treatment suitable to her febrile condition was instituted.

January 13th. The pulse rate was reduced to 72 per minute, but she suffered greatly from nausea, and passed a sleepless night.

January 14th. She complained of severe pain over the præcordia. Urine scanty; specific gravity 10.20; one-fifth albumen by bulk and loaded with urates.

A flaxseed poultice was placed over the region of the heart and potass. bitart was administered in small doses every two hours. Sulphate of quinine was given thrice daily and sulphate of morphia at bedtime.

January 15th, A.M. The temperature was 101.8°, pulse 76 and respirations 36. The pain over the præcordia was very much lessened, but the patient complained of severe pain in the right and left lumbar regions. At this time coarse moist râles were present in both lungs, accompanied by a cough with profuse expectoration of mucus.

January 16th. She was rather better, and from that date she gained slowly, the convalescence being interrupted only on January 22d and 23d, when she had chills followed by sweating. No unfavorable symptoms followed, however, and she was soon able to sit up and her appetite returned. She was given a pill of quinine, arsenious acid and gentian, and the digitalis was continued. She expressed herself repeatedly as feeling better than she had felt for more than two years. She was able to go over the stairs and to walk down town and back. I tried to impress upon her many times the necessity for continuing the digitalis, but she felt so well that she did not see the need of it, and soon after I stopped my visits she stopped all medication.

She had similar attacks on March 7th, 15th and 30th. The pulse on each of these occasions was 140 but was quickly reduced by digitalis or caffeine. The period from April 4th to April 19th was one of great comfort. She was able to walk long distances every fine day and to do her housework with perfect ease.

At this time I considered all her discomfort to be due to the fact that the limit of compensatory hypertrophy had been reached and dilatation had begun, the crippled condition of the aortic and mitral valves having probably originated in the attack of rheumatism three years before.

With the exception of a slight pericarditis in January the patient had with each attack, bronchorrhœa, dyspnœa and various gastro-intestinal disturbances, all of which disappeared as soon as the heart's action was fully under control, and invariably reappeared about one week after she stopped medication.

Repeated microscopic examinations of the urine revealed nothing abnormal.

On the morning of April 20th, I was called to see Mrs. M., and was told that the previous evening just after going to bed, she had a violent chill, that the chill was followed by profuse sweating, severe pain in the right lumbar region, and that she had passed a restless and sleepless night. At this time, about eight o'clock A. M., the temperature was 101°, pulse 140 and irregular, respiration 40. Her face was very haggard and anxious. Orthopnœa was marked, and there was a copious expectoration of glairy mucus. The prostration was so extreme that the physical examina-

[1] Read before the Section for Clinical Medicine, Pathology and Hygiene, of the Suffolk District Medical Society, May 12th, 1886.

tion was necessarily hurried and superficial, but I found on percussion that there was flatness over the lower part of the right chest, and on auscultation mucus and subcrepitant râles over both lungs.

Her stomach was very irritable and it was with difficulty that she retained any food. She was given one of the ammonia salts together with quinine and morphia.

April 21st, there was no improvement and her temperature had reached 103°. I then asked Dr. A. N. Blodgett to see her with me in consultation. A careful examination revealed a slight effusion in the right pleural cavity, œdema of both lungs, and pericarditis friction sounds being present.

The possibility of the existence of ulcerative endocarditis was suggested by Dr. Blodgett. No change in treatment was advised, except with regard to stimulants and milk. These had been tried repeatedly, in various forms, but unsuccessfully; however, we renewed our efforts, but to no purpose.

During the 22d and 23d, she remained in about the same condition except that she grew gradually weaker. On the night of the 23d, she went into a comatose state which lasted until 9 P. M. of April 24th, when she died.

During this illness, which lasted five days, the temperature ranged from 101.5° to 103° there being marked morning remissions and evening exacerbations. The pulse was 140 throughout the attack, and the respirations 40 to 48 per minute.

Orthopnœa was present from the first, but she complained of no discomfort or pain about the heart at any time.

The profuse expectoration was very annoying to her as she could only raise it with great difficulty on account of the prostration. The skin was cold and clammy to the feel and sallow, almost cadaveric in appearance.

Permission to make an autopsy was given at so late an hour, and the time allowed for it so limited, that great haste was required. For this reason the chest only was opened.

Autopsy. Made twelve hours after death. Body fairly well nourished. Rigor mortis present. The lower half of right lung firmly bound to costal pleura by old adhesions; a few recent adhesions were found. The left lung was entirely free. The right pleural cavity contained about a pint of fluid. The left chest was normal. Slight hypostatic congestion over posterior part of lower lobes of both lungs, and both were œdematous.

The pericardial sac contained about ℥iij. of fluid. The heart was increased fully one quarter in size, its walls were hypertrophied and its cavities considerably dilated. On the outer surface of the heart, along the course of the left corronary artery were evidences of inflammation in the shape of little bead-like deposits which were quite firm. Near the apex on the outer surface of the left ventricle was a patch of inflammatory exudate about the size of a small lima bean, which was quite soft. There were several similar patches, though much smaller, at different points of the visceral pericardium, also some cloudiness.

In both auricles and in both ventricles were large ante-mortem clots, the clot in the left ventricle extending into the aorta. The endocardium of the left ventricle showed evidences of recent inflammatory action in the shape of cloudy patches and delicate shreds of plastic matter. The leaflets of the mitral valve showed fibroid induration, the orifice admitting but two fingers.

The ventricular surfaces of the cusps of the aortic valve were the seat of the ulcerative process. In opening the aortic orifice, the incision was made at the junction of the right and left leaflets next the pulmonary artery, dividing one ulcer, the largest one, which measured three-eighths of an inch by one-fourth. It was of a dirty grayish color, and beneath was disintegrated tissue.

The second ulcer was at the junction of the posterior and right cusps.

A little to the left of the middle of the right cusp was a firm mass about the size and shape of a small pea, with beginning ulceration at its apex.

On the posterior cusp were two similar nodules, one of which was slightly softened at the apex, and the other firm.

There were also evidences of inflammation of the aorta extending about an inch and a half from the aortic orifice.

I am glad to lay before the Section the report of this case, with the specimen, for the criticism of its members. It seems to me that the specimen presents *well*, a gradation of the process from the indurated nodule to the open ulcer.

REPORT ON OBSTETRICS.

BY C. M. GREEN, M.D.

THE USES OF ELECTRICITY IN OBSTETRICS, ESPECIALLY WITH REFERENCE TO THE INDUCTION OF PREMATURE LABOR.

SINCE BAYER'S first paper [1] on this subject recalled attention to a therapeutic measure which for a long time had possessed only an historic interest, several observers have embraced every opportunity of testing the efficacy of electricity in its application to obstetrics, and especially to the induction of premature labor. An abstract of Bayer's paper appeared in the *American Journal of Obstetrics* for August, 1885, and the author's method and conclusions are there given in sufficient detail.

A case is reported by WALCHER [2] from the Tübingen clinic, in which the induction of premature labor was indicated in an viiipara whose pelvis was slightly below the average, and whose previous labors had resulted disastrously to the fœtus on account of relative disproportion. Walcher used the constant current of ten elements, introducing the negative electrode (an insulated copper sound with a terminal bulb) into the cervix, and placing the positive electrode over the fundus: each application lasted about ten minutes. Pains were awakened at nearly every sitting and lasted for a varying length of time: the cervix gradually shortened and dilated; and after eleven galvanizations, covering a period of five days, the os was as large as a silver dollar, the membranes bulged, and the labor proceeded. Owing to the transverse position of the fœtus, podalic version was performed. Extraction proving difficult, it was found that the cord encircled the left thigh and prevented the descent of the fœtus: as it was impossible to free the cord, which by this time had ceased to pulsate, it was cut and the

[1] Zeitschrift für Geburtshilfe, u. Gynäkologie, Band xi, Heft 1.
[2] Centralblatt für Gynäkologie, No. 14, 1885.

dead child forthwith delivered. It was then discovered that the cord encircled the child's neck as well, and being of only normal length it was relatively so shortened by these coilings as to cause the dystocia. The fœtus weighed only 7.75 pounds and would doubtless have been born alive but for the accident to the cord. With the effect of the electricity on the uterus Walcher was well satisfied: the mother had a normal convalescence and left the hospital in ten days. It was observed by Walcher as well as by Bayer, that the fœtal movements were usually greatly increased during the galvanization, and perhaps the fatal result to the child in Walcher's case was thus indirectly caused by the electricity leading to fœtal gyrations which resulted in the coilings of the cord.

At the 58th meeting of the Society of German Naturalists and Physicians in Strasburg, 1885, Bayer [3] reported his results in four more cases in which he had used the constant current for the induction of premature labor:

1. In a vpara, in whose previous labors delivery had been effected by version, the children being stillborn, Bayer induced labor at the thirty-sixth week: pains set in after the first application of the constant current, and the os was fully dilated after the sixth. The child was born alive, but died in ten days.

2. Labor was successfully induced with the galvanic current: the child was born alive, but died in six hours of weakness.

3. The os was fully dilated after the seventh galvanization; but the pains continued only during the application, and the method was given up. Three and a half weeks later, however, premature labor set in spontaneously, and the child was born alive.

4. After the ninth application a gray-green ulceration appeared in the cervix: this being healed, another attempt was made, which resulted in a sufficient dilatation of the cervix to admit of operative delivery.

Bayer concludes from his added experience that the constant current awakens pains, dilates the os, and removes strictures of the cervix; but he admits that the results are not uniform. Success is most brilliant when the uterine muscle is in good condition and the cervix is not very rigid. He believes the effect of the current is increased by frequently opening and closing the stream by a rapidly intermittent application of the anode to the abdominal wall: he also uses a double electrode in the cervix. When a number of applications are necessary, the cervix should be frequently inspected, as occasionally ulcerations occur.

Müller, of Berne, discussing Bayer's communication, said that in one case he had had a brilliant success with the constant current; but in his five subsequent cases, after long trial of galvanization, he was obliged to resort to other means in order to awaken pains. Electricity would usually dilate the cervix and there its effect ceased.

Fleischmann [4] has reported from Breisky's Clinic in Prague two cases in which he used the constant current. In his first case, owing to the gradually decreasing irritability of the uterine muscle and to the cicatricial condition of the cervix, galvanism failed to accomplish more than a slight dilatation, and resort was had to other methods. In the second case, having applied the current in the usual manner with only moderate success, Fleischmann tried placing the anode over the lumbar vertebræ and the cathode in the posterior cul-de-sac, using eighteen elements. The result was most satisfactory: effective pains were awakened, and the labor terminated naturally. Applied in this manner, however, the current caused some pain. The fœtus suffered in no way; but its movements were more active.

Apart from its application to the induction of premature labor, Bayer found the constant current of value in regulating and strengthening the pains in labor at term. To promote uterine contractions in the third stage and thus check hæmorrhage, electricity has long been recognized as a useful agent.

In this country, Dr. W. T. Baird,[5] of Albany, Texas, has written an extended paper on this subject, based on an experience of 220 cases. Unlike the authorities previously quoted Baird uses the faradic current, and applies one electrode over the lumbo-sacral region and the other over the abdominal wall, especial care being taken "never to make the application in such a manner as to include the head of the fœtus in the circuit." Baird believes that electricity has a very extended field of usefulness in obstetrics, in short, in any case in which it may be desirable

"1. To modify the pains of labor."

"2. To favor a more rapid dilatation of the os."

"3. To promote more vigorous uterine contractions."

"4. To add tone and strength to all the muscles engaged, and increase their power of doing work."

"5. To abridge the time occupied by the labor."

"6. To prevent shock, exhaustion, and post-partum hæmorrhage."

"7. To insure contraction of the uterus in cases of instrumental delivery."

"8. To act as an auxiliary in the induction of premature labor."

"9. To arrest hæmorrhage and accelerate labor in cases of placenta prævia."

"10. To prevent an undue expenditure of nervous force, in all cases of debility from whatever cause, thus leaving the patient in a condition to secure a speedy and favorable convalescence."

THE ÆTIOLOGY OF FACE PRESENTATIONS.

Hoffheinz [6] in his inaugural dissertation has analyzed the material of the Königsberg clinic for the years 1866 to April, 1884, finding the large proportion of one face presentation to one hundred and seventy-nine of all others,— in all fifty-eight cases. The face presented more frequently in multiparæ than in primiparæ; but the mother's age had no definite ætiological influence. It is undecided whether the premature rupture of the membranes, so frequent in face presentations, and the consequent delay in the first stage are to be ascribed to the faulty engagement of the head, or to contractions of the pelvis, which frequently complicate these cases. The author believes that the possible causes of face presentations can be stated with tolerable certainty as follows:

a. Marked lateral deviations of the uterus.

b. Contraction of the pelvis in its conjugate diameters.

c. Unduly great weight of the fœtus in proportion to its length.

[5] American Journal of Obstetrics, April, May, and July, 1885.
[6] Centralblatt fur Gynäkol., No. 46, 1885.

d. Prolapse of a hand beside the head.

e. Dorsal displacement of an arm.

It is questionable whether multiple coiling of the cord can cause face presentation; and Hecker's theory, that dolico-cephalism is a primary cause, seems to the author improbable.

MALARIA AND PUERPERALITY.

BONFILS[7] (Thèse de Paris, 1885) has treated this subject very fully, basing his conclusions on an analysis of one hundred and forty cases. Pregnancy and malaria can certainly exist simultaneously without reciprocal influence; but in a certain number of cases this influence is manifest. The effect of the malarial poison on pregnancy is not so much in causing abortion, as many authors believe, (Bonfils found only twelve instances in one hundred and five cases), as in provoking premature labor (sixty-one times in one hundred and five cases). The accidents are oftener occasioned by progressive malarial cachexia, than by visceral and placental congestions produced by the intermittent paroxysms; this influence manifesting itself in the death of the fœtus (observed twenty-four times in one hundred and five cases), and in fœtal malnutrition, whereby the weight and length fall respectively, in the average, one pound and four inches below the average weight and length of healthy infants: in only nine cases in one hundred and five did fœtal death occur in apparent consequence of the intermittent paroxysms. Intra-uterine infection of the fœtus by the malarial poison is rarely observed. On the other hand it is still debatable whether or not the poison can be transmitted to the newborn through the mother's milk.

The extent of malarial influence on labor is not yet clearly demonstrated; but the author asserts that post-partum hæmorrhages are often observed, that uterine involution is retarded, that the lochia remain bloody for a longer time, that the milk is less abundantly secreted and of poorer quality. While pregnancy and labor are not necessarily secure from acute malarial attacks, it is in the lying-in period above all that they appear. In the first three weeks, and especially during the first days, acute attacks are most frequently observed. Malarial cachexia often makes rapid progress in this period and gives rise to progressive pernicious anæmia.

THE PROPER RELATION OF VERSION AND EXTRACTION IN POINT OF TIME.

It has been held by some authors that after version from either transverse or cephalic presentations it is better to wait for a time before proceeding to the manual extraction. Or in other words, that in cases in which malpresentations require correction, it is better to do pelvic version (externally or bimanually) before the os is fully dilated and then wait for full dilation before proceeding to the extraction, if such interference is necessary. With a view to demonstrating the inadvisability of this separation of the two operations in point of time, WINTER[8] has analyzed the material of the Royal University Clinic in Berlin from 1876 to 1884 and collected three hundred and ten cases of simple, uncomplicated transverse positions of full-term living children: from the examination of this material he has come to the following conclusions:

1. The teaching, that version and extraction should not be performed in immediate succession, arose from the false supposition that the footling case produced artificially by version has the same prognosis as the same presentation occurring naturally.

2. The earlier and generally adopted practice of performing version as soon as possible after the escape of the liquor amnii rests on the fear of the intra-uterine death of the fœtus and especially of the increased difficulty of version after longer waiting.

3. Fœtal death does not occur alone from the premature escape of the liquor amnii, but only when tympanites uteri, unduly powerful pains, or tonic uterine contraction complicate the case.

4. Version cannot be rendered difficult by waiting until the dilatation of the os, for the dangerous thinning of the lower uterine segment does not occur until the expulsive stage; nor again does the ordinary clonic uterine contraction cause trouble in turning. Tonic uterine contraction, however produced, is a pathological condition, which is always to be avoided.

5. In normal cases children bear version and immediate extraction with safety.

6. Waiting after version before proceeding to extraction is very dangerous for the child, which often dies in utero, or is saved only by speedy extraction.

7. The causes of fœtal death are injuries to the cord during the version, separation of the placenta, and entrance of air into the uterus.

8. Whether the membranes are ruptured or unruptured version should not be performed until the extraction can be immediately proceeded with.

9. Only a definite indication, such as placenta prævia, prolapse of the cord, beginning infection, imminent asphyxia of the child, great thinning of the lower uterine segment, pure inertia uteri, demands early version, that is, before the dilatation of the cervix, and then for the most part in the interest of the mother.

Clinical Memoranda.

A CASE OF EXTRA-UTERINE PREGNANCY.[1]

BY E. A. KEMP, M.D.

AT half-past eleven A. M., on the 25th of March, I was called to see Mrs. P., a lady about twenty-six years old. Had been married about three months. On my arrival, I found the patient lying on the bed; pulse not very weak, and still not as strong as you would expect in a healthy woman. Heart sounds normal. There was a pallor about the face, how marked I could not say, as I had never seen the patient before. Hands and feet were quite cool. I gleaned the following history from her mother, who had come in a short time before the patient's illness. She had always been healthy, and was chatting and laughing with her mother and another lady when the grocer called. She arose rather hastily, went to the door, transacted whatever business she had, and started to return. While in the entry, she came near falling, when her mother assisted her to the bed in an adjoining room. She complained of an occasional pain in the region of the stomach, saying that it would pass to the right shoulder. There was belching of wind; in fact, it seemed like a case of

[1] Read before the Essex South Medical Society, Danvers, Mass.

indigestion, and as I had seen a lady the night before who had fainted and was nearly pulseless, which proved to be a case of indigestion, I could hardly feel alarmed at the symptoms developed by my patient.

After the application of heat to the extremities, and administering remedies which seemed appropriate, she was very comfortable, and when I left, seemed as well as one could expect under the circumstances. About eight in the evening, the husband came to my office, and said that the pain in his wife's stomach had not entirely ceased, and thought I had better see her, so I immediatly went home with him. Found the patient quite pale, hands cold, but feet warm. Some pain at intervals in the region of the stomach, radiating to right shoulder. Heart sounds and pulse quite weak. In fact, she had every appearance of a woman losing blood.

A careful examination revealed nothing. Both herself and mother informed me that she had been regular in her monthly sickness, and that the regular monthly flow had ceased only a day or two before. I watched her for an hour, doing whatever the case seemed to demand by stimulants, etc., but everything that was done apparently did no good. The case seemed very critical, and I kept thinking, "I am afraid she will die"; but the thought would come, how can she die without a cause, and what is the cause? I requested the husband to go to Dr. Frost's, about one-fourth of a mile away, and ask him to come and bring some ammoniac, as I had used my last. During his absence the patient was pulseless at times, and one of the heart sounds only could be heard; but under the administration of hypodermic injections of whiskey, both heart sounds strengthened so as to be heard distinctly, and the pulse greatly improved. After Dr. Frost's arrival, we worked on for an hour and a half without any apparent benefit, when Dr. Carlton arrived; but our united efforts, by means of stimulants, both by mouth and hypodermically, with hypodermic injections of digitalis, together with inhalations of nitrite of amyl, all seemed to be of no lasting benefit, and at 2 A. M. the patient died; and we could only say that she apparently died from loss of blood, but from where the most careful examination failed to reveal.

About twenty hours after death, a post-mortem examination was made. There were present Drs. Frost, Carlton, and Atwood.

Rigor mortis was present. The surface was unusually blanched. On opening the abdominal cavity, a quantity of dark fluid blood immediately escaped; a large quantity of fluid blood remained in the lower part of the abdominal cavity. Both iliac fossæ were completely filled with clots. On a careful removal of the clots, we found a case of tubal pregnancy, with rupture. I should judge the pregnancy had advanced to the sixth week. I show you the specimen, which gives you a good idea of the case. It seems to me that the interesting features of the case are these: The woman's perfect health, without the least disturbance as regards pregnancy, that is, without symptoms. The regularity in her monthly sickness (at this time the monthly flow had just ceased). Also the early rupture.

The following report upon the specimen was made by Dr. W. F. Whitney, Curator of the Warren Anatomical Museum:

"The specimen consisted of the uterus and adnexa.

"In the right ovary was a corpus luteum about 1.5 cm. in its longest diameter, having a sinuous, linear, yellow, central portion surrounded by dense, whitish, connective tissue.

"Projecting from the upper part of the uterus, at the place where the right Fallopian tube joins the fundus, was a tumor the size of a hen's egg; at the upper anterior aspect of this the wall was exceedingly thin, and had evidently ruptured. The part of the wall towards the uterus was thicker, and composed, in part, of uterine tissue. The interior of the tumor was filled with a shreddy mass, recalling placental tissue. (It was reported that a small, embryonic structure was found attached to this by a fine thread at the time of the autopsy).

"The lining membrane of the uterus was smooth, velvety, and much thickened. The walls, however, were but little increased in thickness, nor was the cavity enlarged."

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY. SUFFOLK DISTRICT. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

ALBERT N. BLODGETT, M.D., SECRETARY.

May 12th, 1886.

Meeting called to order at 8 o'clock, by Dr. F. I. Knight, Chairman. The records of the last meeting were read in summary by the Secretary and approved. Previous to the papers of the evening, the Chairman announced that Dr. Bowditch desired to address the Section.

Dr. Bowditch said that he had three articles which he would present to the Section, two of which would be hereafter placed in the portfolio of the Boston Medical Library. They all held important relations with the history of medicine, and he thought they would be interesting to the members.

First. A splendid lithograph of Vesalius, "The Father of Modern Anatomy." No one could look at it without feeling that if Vesalius had not been great in our profession, he would have been great in any walk of life. One could believe from his fine commanding brow and calm look that he might have been a statesman. He was born in Brussels in 1514, and died in 1564 of starvation in the Island of Zante, where he had been shipwrecked on his return from a pilgrimage to the Holy Land. Accused by the minions of the Inquisition of having begun to dissect a man while the heart was still palpitating, he was saved from death only by the favor of Philip II, to whom he was chief surgeon. He had taught anatomy at Pavia, Bologna, and Pisa from 1540 to 1544, and had large crowds of students to hear him. His immortal work "De Corporis Humani Fabrica," in seven volumes, was first printed at Basle in 1543. Boerhaave and Albinus published another edition in folio in 1725 at Leyden.

The second article shown was a pharmacopœia published at Cologne with Petrus Holzeming as editor, a worthy man doubtless, but now wholly unknown to fame, so far as biographical dictionaries are able to tell us. It is a thin folio volume, with large, well-engraved title-page. At the top are the armorial bearings of Cologne. Below is a view of the city. On the sides are four physicians, namely, St. Luke, St.

Parataban, St. Agmar, and St. Damianas. The last three suffered martyrdom in the fourth century. St. Connes was for many years the patron saint of physicians. A church dedicated to his memory in the 13th century, was taken down in 1832. At one time the fraternity of priests of St. Connes taught medicine there. Ambroise Paré in the 16th century gained his title of Master Surgeon from that Faculty. The pharmacopœia is a most interesting work, as illustrative of the absurd lengths our fathers in medicine went in the number of articles put in their prescriptions. Generally speaking there were one or two active ingredients, as aloes, opium hyoscyamus, etc., in a prescription, and the remainder were inert. The most remarkable in the book is an electuary powder. It contains fifty-four different ingredients and was styled "Pulvis Subtilissimus."[1] In this prescription, human nature had evidently gone to the utmost extreme of over medication. The whole book with its absurd remedies seems to prophesy homœopathy, with its single and equally absurd infinitesimals. Man never goes toward the truth in a straight line, but in a pendulum course.

Third. A photograph of a painting by Watteau, caricaturing in pencil after Moliere had done so with his pen, the absurdities of the faculty and the extremes to which the public were led by eulogiums on the use of the "clystere." Moliere wrote his "Malade Imaginaire" for the opera of the king and noblesse. Watteau, coming after him a few years, painted the scenery on the same stage. The painting which the photograph represents is in the museum at Lille in France. It shows an immense army of people coming to meet the great Doctor, who is dressed in fur-bordered robe, with feathers in his hat. He stands erect with an immense gravity and important look. His right arm extended as if giving decided directions in regard to a patient who is about to have an enema given to him. An immense crowd looking like an army covers the background. Each person armed with a huge syringe, instead of the usual trappings of war. Upon the top of the staff, bearing the color of the regiment, instead of the imperial eagle appears an upturned chamber utensil which shall be nameless. Various groups are seen in the foreground, of a most realistic character. A lady with glutei and legs exposed, and two negroes administering an enema. A lady with her lapdog on her arm, and her husband are apparently leaving the scene, but are followed by an attendant of the doctor, armed with a syringe, who is evidently entreating her to allow him to give her an enema. On the other side of the picture is a burly postman, set upon by two attendants, one of whom has pulled the hat over the eyes of the struggling victim, while the other is preparing to give him the injection, which one sees the postman will not readily submit to. But most comical of all is a poor, evidently costive dog, with curved back, plainly striving in vain for a dejection, and mutely appealing for an enema for his relief. One has only to read the "Malade Imaginaire," of Moliere, to get a full explanation of this gross caricature. At the same time it shows the absurd length to which our fathers went in regard to the rectum, as according to the pharmacopœia above described, they had a half century or more before, filled the mouths of their patients with their subtle powders. Who can wonder at homœopathy and electicism in consequence of such nonsense.

DR. S. W. LANGMAID moved a vote of thanks to Dr. Bowditch for his very interesting remarks, and his valuable and unique gifts to the Section.

The motion was put by the Chairman, and carried unanimously.

DR. GRACE WOLCOTT read a paper on,

A CASE OF ULCERATIVE ENDOCARDITIS.[2]

DR. F. C. SHATTUCK, upon being invited to open the discussion, expressed his interest in the well reported case which had just been read. The pathology of endocarditis in general presents problems, at once interesting and difficult, to the solution of which we thought ourselves nearer some years ago than we do to-day. Until lately the real distinction between ulcerative and simple endocarditis was thought to lie in the presence in the former of micrococci; and the term diphtheritic endocarditis was proposed to characterize the process at one time. To these organisms the infectious nature of the affection was attributed; to them it was thought to be due that emboli excited suppurative inflammation about their points of lodgment. This distinction now fails us since Klebs, Köster, and others find micrococci in the products of any and every endocarditis, without having succeeded as yet in distinguishing between those accompanying forms which are clinically so different. Anatomically the difference is rather one of degree than of kind, and hence Osler prefers the term malignant to the term ulcerative. In an endocarditis of malignant course there may be no more ulceration than in a benign case of warty endocarditis; and, on the other hand, there may be well-marked ulceration from very different causes. The main anatomical distinction is in the different results of embolism; as to the pathological distinction we are at present ignorant; the clinical distinction is more clearly marked. Thus we are led to the eminently practical question of diagnosis. In some malignant cases the diagnosis may be made with tolerable certainty. We know that the process is especially liable to attack valves which are the seat of changes dependent on previous disease, notably sclerosed valves; and hence grave typhoidal or pyæmic symptoms, for which no other cause can be assigned, in an individual known to be the subject of old valvular disease are, to say the least, suggestive. Similar symptoms with indications of embolic abscesses in a case of acute rheumatic endocarditis are, in like manner, suspicious; but this association is, according to Osler, rare. In cases of primary malignant endocarditis the diagnosis may be reached by a happy guess, but is generally beyond our powers. The general symptoms vary very widely in different cases; simulating typhoid fever, pyæmia, malaria, or some other general infectious disease; the leading symptoms may be cerebro-spinal; symptoms pointing to the heart may be wanting or excessively obscure. If the heart was previously healthy the organ is not enlarged and the course of the disease is usually too short to allow it to become so; while a souffle can easily be attributed to so called dynamic causes. A case which recently occurred at the Massachusetts General Hospital, in the service of Dr. Abbot, the autopsy on which the speaker attended, well illustrates the impossibility of diagnosis at times. A woman

[1] Duke Don Nicholas, so called because prepared by an Abbot for the son of Don Nicholas.

[2] See page 25.

died after an illness of ten days or so, with ill-defined but rather typhoidal symptoms and no indication of cardiac disease. Primary ulcerative or malignant endocarditis limited to the tricusted valve with emboli in the lungs was found. The speaker had seen two or three cases in life in which he had suspected this form of disease, but had not been so fortunate as to secure an autopsy to overturn or confirm the diagnosis. He congratulated Dr. Blodgett both on the diagnosis in the case just reported and on its verification.

Dr. E. G. Cutler expressed much interest in the case reported. He had never seen an instance of ulcerative endocarditis at autopsy, but had had, a few years ago, a patient under his care with the following history: a child of six had passed through an attack of mumps, under another physician, two other children were sick with the disease about the same time. Some days afterwards the child, having been all the time ailing, was seized with chills, fever, pain in the præcordia, and restlessness. There was found to be a loud systolic murmur at the apex. The patient got worse, the circulation in one of the arms suddenly ceased, accompanied by pain and swelling. The femoral artery in one of the legs became plugged soon after, associated with severe pain. The murmur ceased before death, which occurred about a week after the patient was first examined.

Dr. H. I. Bowditch stated that he had never seen a case of this disease in his life, and that the condition was unknown to him. The specimen was a most interesting one, and showed a new source of danger in diseases of the cardiac tissues. Dr. Bowditch asked if the diagnosis of ulcerative endocarditis were made before death, and if so, on what grounds was this opinion based?

Dr. Blodgett replied that he had the privilege of examining the patient before death, and from the history of a long-continued organic disease of the heart which had been studied by careful physicians for many months, to which a new and most serious complication had been suddenly added, he was led to review the conditions to which this unexpected change might be due. The character of the symptoms observed at this time was essentially that of acute septicæmia; that is, there was acute pain in various parts of the body which were not before the seat of disease. The pulse and temperature were very high, the patient was in a condition of stupor, almost amounting to apathy, and resembled the state called "typhoid" in many asthenic diseases. The array of symptoms thus calling attention to a condition so closely approximating to that of surgical pyæmia, it seems only a short way to the diagnosis which alone would sufficiently explain the symptoms. The autopsy was of necessity very hastily made, and gave no time to examine the other visceral organs, which might possibly have shown other interesting pathological conditions connected with the state of the heart.

Dr. Shattuck observed that in any case of endocarditis we may have embolic formations in the blood-vessels. In benign endocarditis the emboli do not occasion suppuration, while in the form of endocarditis which we may for the sake of comparison call "malignant," the emboli are followed by suppuration, and the appearance of a train of clinical phenomena bearing considerable resemblance to septicæmia.

(The remainder of this report will be published in connection with the paper to which the discussion refers).

ASSOCIATION OF AMERICAN PHYSICIANS.[1]

SECOND DAY.— AFTERNOON SESSION.

PERI-UTERINE INFLAMMATION,

by William Polk, M.D., of New York.

The purpose of the paper was to consider those masses found about the roof of the vagina, generally to the sides of the uterus, sometimes behind, rarely in front. These have been described under the head of pelvic cellulitis and peritonitis, and have been the cause of much controversy. The speaker considered these masses to be the result of salpingitis due to uterine disease. Under ordinary circumstances, the disease travels by way of the tubes, but in septicæmia it travels by all routes. Fifteen cases were reported in which the symptoms and signs ordinarily ascribed to pelvic cellulitis and peritonitis were present, but in which opening of the abdomen showed salpingitis, peritonitis, and ovaritis, there being no thickening of the cellular tissue. Except in those cases in which there was shortening of the ligaments, the uterus presented about the normal mobility. Pelvic abscess, in the writer's opinion, was, in the majority of cases, of tubal origin.

As regards the causation of these masses, anything that will produce endometritis may produce salpingitis and cause these masses.

Prognosis. Death is the exception. This result is to be expected when septicæmia is the cause of the trouble, or when there is a depraved state of the system. The occurrence of abscess is usually followed by recovery. If the mass remains, the permanent cure of the case is doubtful.

In chronic cases, after all other measures have failed, operation may be performed. The tubes need not necessarily be removed. The tearing of the adhesions may be sufficient.

Conclusions: Salpingitis is neither a new nor a rare disease.

It is, with peritonitis, the most common form of inflammation about the uterus, holding, in point of frequency, almost the same relation to the extra-uterine surface as does endometritis to the intra-uterine.

The majority of cases get well.

A small number do not get well, and these are capable of causing such danger and distress to the patient, that abdominal section and removal of the uterus and ovaries is a necessity.

AN EXPERIMENTAL STUDY OF GLOMERULO-NEPHRITIS,

by W. H. Welch, M.D., of Baltimore.

Of the various processes which make up the pathological anatomy of Bright's disease, the two which, at present, awaken the greatest interest, and the study of which promises the most fruitful results, are probably the changes which take place in the glomeruli, and atrophy and necrosis of the epithelial cells.

The questions which have not as yet received full and satisfactory answers, are, what is the origin of the cells which often, in nephritis, occupy the space between the glomeruli and the capsule of Bowman? Does migration of the white corpuscles or diapedesis of the red corpuscles take place through the glomerular capillaries? What relation as to frequency and intensity do changes in the glomeruli play in the pathology of Bright's disease? In expectation that light might

[1] Concluded from page 14.

be thrown upon these questions, the speaker had experimented on rabbits and white mice, by the production of acute cantharidal poison. A concentrated solution of cantharidin in acetic ether was employed by subcutaneous injection. After a toxic dose, the urine diminishes, and is finally suppressed. It contains albumen, hyaline casts, and a large number of leucocytes and red blood-corpuscles.

Microscopical examination of the kidney in the rabbit shows here and there foci of infiltration, with small, round cells, doubtless migrated white blood-corpuscles. The epithelium of the convoluted tubes is, in places, normal in appearance; in other places it is swollen, and often the inner part of the cells is broken off, appearing as a granular mass in the lumen of the tube. The most marked change is found in the malpighian bodies. In the greater number of these, there is between the glomerulus and Bowman's capsule a wide space, partly or wholly filled with cells. These are larger than white blood-corpuscles. They are frequently arranged in a crescentic mass. These appearances are similar to those described in glomerulo-nephritis in man. In the latter case, these cells are attributed to the swelling and desquamation of either the capsular or glomerular epithelium. Such explanation does not hold in the present case. The epithelium of the capsule is often intact, and the glomerular epithelium may retain its normal position. More frequently, it is swollen and may desquamate. There are no appearances which justify the derivation of the greater number of the cells from the epithelium of the glomerulus. These cells cannot be regarded as white blood-corpuscles changed by the action of the poison, for the cells circulating in the blood are exposed to the same poison. These cells may be derived from the epithelium of the convoluted tubes in immediate communication with the malpighian bodies. The cells in the capsular space are identical with those in the convoluted tubes. At times, there can be found groups of cells arranged in the form of a ring, with a central space, just like the epithelium of the uriniferous tubules.

It is difficult to decide whether the cells occluding the glomerular capillaries in acute and chronic Bright's disease are white blood-corpuscles or endothelial cells, but the speaker inclined to the view that at times they are detached endothelial cells. Swelling of the endothelium, and accumulation of cells in the glomerular capillaries appears to be a nearly constant lesion in the acute nephritis of scarlet fever. In one case examined, this was almost the only lesion in the kidney. Occasionally pathologists meet with kidneys in which the apparent changes do not explain the symptoms. In such cases, careful examination of the glomerular capillaries should be made. It is difficult to think of any lesion of the kidney more destructive to its function than occlusion of the capillaries.

While disposed to attach much importance to the changes in the glomerular capillaries, we are not justified in asserting that these changes constitute the primary and essential cause of Bright's disease. They are coördinate with other lesions.

He suggested that instead of the term glomerulo-nephritis, the term glomerulitis be used. The form characterized by accumulation of the cells between the glomerulus and Bowman's capsule may be designated desquamative glomerulitis, and that characterized by the accumulation of cells, or by other changes within the capillaries, may be called intra-capillary glomerulitis.

BICUSPID CONDITION OF THE SEMI-LUNAR VALVES, AND ITS RELATION TO AORTIC VALVE DISEASE,

by WILLIAM OSLER, M.D., of Philadelphia.

A bicuspid condition may be said to exist when two of the three sigmoid cusps have more or less perfectly fused, so that the arterial orifice is guarded by only two segments. The points alluded to were, first, the frequency of the condition. The abnormality is a well-recognized one. Dilga recently collected the statistics, and has found sixty-four cases of this condition in the pulmonary artery, and twenty-three in the aorta. This statement gives an incorrect idea of its frequency in the latter vessel. In over eight hundred autopsies at the Montreal General Hospital, there were eighteen cases, seventeen in the aortic valves alone; in one, pulmonary and aortic segments were both involved. In one hundred and ten cases of valvular disease of all kinds, there were fifty-seven in which the aortic valves were affected, so that this condition existed in over thirty per cent. of all cases of aortic valve disease.

Second, the clinical history. The part played by this condition in aortic valve disease is illustrated by the history of the eighteen cases. Two died suddenly from cardiac syncope. Twelve presented the picture of chronic aortic insufficiency, and in four the lesion was accidentally found, death having resulted from other causes. In sixteen cases, there was hypertrophy of the heart, chiefly of the left ventricle. With the exception of one case, a fœtus at the eighth month, the patients were adults. The ages ranged from twenty to sixty years. This contrasts in a marked manner with the history of this defect in the pulmonary artery. A great majority of the instances present other serious anomalies of development, and death takes place before puberty.

Third, the mode of origin of the lesion. Unquestionably, the majority of the cases are congenital, and result either from faulty development or a fœtal endocarditis. The former view seems the more probable (a) from the fact of the existence of the condition in fœtal life without any traces of endocarditis; (b) the occurrence of all grades of the condition from fusion of the attached terminal margins of contiguous segments to perfect fusion of the cusps, with scarcely an indication of the line of union; (c) a comparison between the size of the conjoint and single cusps indicate that the anomaly must take place at a very early period of development, as in some instances, the single valve equals, or is even larger than the fused segments, while in others the slight inequality in size is scarcely consistent with the view that a fœtal endocarditis, subsequent to the formation of the valves, had caused coalescence of the curtains. We do not know accurately the details of the development of the sigmoid valves, but Tonge's interesting observation on the chick showing that two of the cusps are formed before the third, may have some connection with the production of this anomaly.

THE BACILLUS OF TYPHOID FEVER,

by GEORGE M. STERNBERG, M.D., U. S. A.

Recent researches support the view that the bacillus described by Eberth in 1880, bears an etiological relation to enteric fever, although the final proof that

such is the case, is still wanting. This proof would consist in the production in one of the lower animals of the specific morbid phenomena which characterizes the disease as it occurs in man, by inoculation of a pure culture of the bacillus. Thus far, we have no evidence that any one of the lower animals is subject to the disease as it occurs in man; but Frænkel and Simmonds have shown that the bacillus of Eberth is a pathogenic organism and that pure cultures injected into the peritoneal cavity of mice or into the circulation of rabbits, causes the death of these animals and that colonies of the bacillus are found in the spleen, which resemble in every respect the colonies found in the spleen and other organs of typhoid cases.

The researches of Eberth, Meyer, Gaffky, Frænkel and others, indicate that this bacillus is constantly present in the intestinal glands and in the spleen of typhoid cases, and Gaffky has shown that pure cultures may be obtained from the spleen, even in cases in which a microscopical examination fails to demonstrate the presence of the characteristic colonies.

The researches of Brieger show that a toxic ptomaine is produced as a result of the vital activity of Eberth's bacillus, when it is cultivated in albuminous culture media. This injected into guinea pigs, causes salivation, diarrhœal discharges, debility, dilated pupils, rapid respiration, and death at the end of twenty-four or forty-eight hours.

Demonstrated facts relating to the propagation of typhoid fever, indicate that it is due to an organism which is capable of multiplication external to the human body in a variety of organic media at comparatively low temperatures. Eberth's bacillus complies with these conditions, in consideration therefore, of its constant presence and the absence of any other organism as shown by microscopical examination and culture experiments, the inference seems justifiable in the present state of science, that this bacillus bears an etiological relation to the disease in question.

A CLINICAL REPORT OF NINE CASES OF HEMIANOPSIA,

by DR. E. C. SEGUIN, of New York.

He presented an abstract of nine cases of lateral hemianopsia due to cerebral lesion, and called attention to the following points of interest:

First. Of the nine cases, five had right lateral hemianopsia, and four left lateral hemianopsia.

Second. Three of the cases of right-sided hemianopsia presented the following association of symptoms: hemianopsia, right sided hemiparesis with post-paralitic ataxia and partial hemi-anasthæsia. Two of these cases also exhibited ataxia without other aphasic symptoms. It is interesting to note that all cases of right-sided hemianopsia do not have ataxia, and also that post-paralytic ataxia is not always accompanied by hemianopsia, though probably this is more common than is generally supposed.

Third. The six other cases were practically cases of pure hemianopsia, that is, there were no paralytic or sensory symptoms or aphasia indicating extensive cerebral disease.

In the first category the lesion is probably placed on the outer edge of the thalamus, so as to involve the fasciculus opticus and the posterior division of the internal capsule. In the second category, the lesion is quite certainly further back or in the white matter of the occipital lobes.

Fourth. In two cases of the second category, marked and increasing weakness of both legs was present, a symptom perhaps due to the upward and forward extension of a tumor toward the para-central lobule.

Fifth. A very peculiar symptom in two cases of the second category, and one which the author thinks is new, was the occurrence of hallucinatory images for a short time in the darkened half-field. This is a symptom of irritation and analogous to the convulsive movements which sometimes precede paralysis of a limb when its motor centre is being destroyed by disease.

Sixth. Ophthalmoscopic changes were observed in only one case of the second category. In this case, neuro-retinitis developed in both eyes under the physician's observation, about one month after the first visit.

Seventh. In no case was the hemiopic pupillary reaction of Wernicke, observed.

Eighth. A special pathological question came up in one case of the second category. In 1883, the patient had glaucoma with irregular hemiopic defect, first in one eye, and later in the other, and yet only fourteen months later was pure geometric hemianopsia found. Could glaucoma produce this? The speaker thought not; being unable to conceive how intra-ocular pressure could so affect the retina and optic nerves as to produce a strictly hemiopic defect in dissimilar halves of each eye. A central lesion is quite certain.

Ninth. A very puzzling point is the perfection of central vision in these and other cases of central hemianopsia. The vertical line always passes by the point of fixation, no matter on which side the blindness is. We must conclude that the macula is not involved in the loss of function, and the question arises. can the macula have a double innervation from the visual centre? This point the author intends to study thoroughly.

The speaker also exhibited specimens illustrating the seat of lesion in certain cases of hemianopsia.

DR. HENRY FORMAD exhibited specimens of kidneys demonstrating some peculiarities of

CYANOTIC INDURATION OF THOSE ORGANS.

This condition is produced by anything which interferes with the circulation through the kidneys. The shape of the kidney where the cyanotic induration results from alcoholism is rounded and shortened. The kidney presents a "pig-back" appearance. Where the cyanotic induration results from heart disease, the shape of the organ is not altered, as the condition takes place gradually.

The following papers were read by title:

NOTES OF A CASE OF HEPATICO-BRONCHIAL FISTULA,

by DR. J. E. GRAHAM, of Toronto.

PANCREATIC HÆMORRHAGE AS A CAUSE OF SUDDEN DEATH,

by DR. F. W. DRAPER, of Boston.

PERNICIOUS ANÆMIA,

by DR. A. JACOBI, of New York.

A CASE OF HODGKINS' DISEASE,

by DR. F. FORSHEIMER, of Cincinnati.

A vote of thanks was tendered the government officers and the profession of Washington for courtesies extended.

Adjourned.

NEW YORK COUNTY MEDICAL ASSOCIATION.

STATED meeting, May 17, 1886.

EXTRA-UTERINE FŒTATION, WITH ILLUSTRATIVE CASE.

DR. WILLIAM T. LUSK exhibited the specimens and related in detail the history of a case of extra-uterine fœtation, which, he said, presented a great many points of extreme interest. The patient was a lady residing in Wisconsin, thirty-five years of age. She had been married fifteen years, and for fifteen years had had perfect health. In September, 1883, she missed a menstrual period for the first time, and one month later she suffered from very violent pains. Not long afterward she had two or three attacks of paroxysmal pain, radiating from the right side, and on one of these occasions, (October 27), it was of extreme severity and lasted for two hours.

The last attack was on November 7, and she then began to improve in health. She passed two menstrual periods, and presented all the signs of pregnancy. Until the following July she did not have a single bad symptom. On June 17, however, the fœtal movements, which had previously been of the most marked character, were felt for the last time. About the middle of July she supposed herself to be in labor, and sent for her physician, Dr. Meade, who, on making an examination, found the uterus quite high up. The cervix was somewhat softened, but the pains were false; and he therefore left her until the following morning. He then ascertained that the uterus was empty, and that there was a tumor outside of it. The possibility of extra-uterine pregnancy occurred to him, and, under the circumstances, he called in Dr. Marks, of Milwaukee; but a positive diagnosis was not arrived at.

In September, 1884, she went to Chicago and consulted an eminent gynæcologist, who strongly insisted that there was no extra-uterine pregnancy, and made the diagnosis of cysto-fibroma of the uterus. In February, 1885, she came on to New York and placed herself under the care of Dr. Fordyce Barker, who at once recognized the case as one of abdominal pregnancy, and invited Drs. Thomas and Lusk to examine the patient. They concurred in the opinion of Dr. Barker, and she was advised to return to New York in the following June or September for the purpose of having an operation performed.

After her return home she suffered from what was called remittent fever, but which, in view of the condition of affairs found at the autopsy, indicating prolonged septicæmia, Dr. Lusk could not doubt was in reality the effects of putrid absorption. In the following autumn her health appreciably failed. The pulse became very rapid, and she had a good deal of diarrhœa, as well as nervous disturbance. In December she was persuaded to go to Chicago and consult the same gynæcologist again. He now modified his diagnosis, agreeing with that of the New York physicians; but urged the patient under no considerations to submit to an operation. He informed her that in four cases in which he had himself operated the result had proved fatal, and expressed the opinion that she would not survive an operation. He also encouraged her to believe that she was in no danger, and advised her to go South and live out of doors as much as possible. Accordingly, she went to Atlanta, but during the three months that she was there she was unable to go out of her room. She gradually grew worse, but succeeded in arriving alive in New York in the early Spring. The change of air seemed to have a beneficial effect, and she so far improved that for a short time she was able to go down to one meal a day.

It was three or four days after her arrival that she first sent for Dr. Lusk, and when he saw her he was at once struck with the marked change which had taken place in her condition. She had a pinched appearance, and was extremely anæmic. The pulse was quick, and there was a rise of temperature every evening. There was also constant diarrhœa, or else diarrhœa alternating with constipation. Very shortly a menstrual period came on, and this was attended with the most marked constitutional disturbance. The temperature ranged from 103° to 104°, the pulse was extremely feeble, and there was enormous distension of the abdomen. The tumor also increased very greatly in size. The husband, however, assured Dr. Lusk that there was no occasion to be alarmed, as the same disturbances had been noticed at previous menstrual periods, and had been successfully rallied from.

It was agreed, therefore, that she should be removed to St. Elizabeth's Hospital, and that one week before the expected time of the next menstrual period an operation should be performed; this time being set in order to allow her to recuperate as far as possible from the exhaustion incident to the serious febrile condition mentioned. Unfortunately, however, the husband's predictions were not verified, and from this time she declined steadily in health and strength. Drs. Thomas and Barker were called in consultation, and agreed with Dr. Lusk that, on account of the exhausted state of the patient, an operation offered no hope of recovery, the chances in its favor being almost one in a thousand. The idea of operating was, therefore, abandoned.

Later the husband asked Dr. Lusk how long he thought his wife could live, and when the latter informed him that it would be impossible for her, in her present condition, to survive another menstrual period, he insisted that an operation should be performed, as offering the only possible chance (however remote) of recovery. Accordingly, on the 19th of March, much against his will, Dr. Lusk operated.

The tumor at this time occupied pretty much the entire abdomen, and seemed to be equally extensive on both sides. The incision was made in the median line, below the umbilicus; and it was noticed the fluid from the vessels of the tissues severed, was almost colorless, like serum. The abdominal walls having been cut through, the tumor was observed, with portions of the fœtus shining through. It was found to be entirely free from adhesions to the abdominal walls, and on this account the question arose whether it would not be advisable to remove the tumor entire. Fortunately, as the sequel proved, this course was not adopted, and when an incision was made into the sac, a volume of horribly fetid gas escaped. There was no fluid, except about a tablespoonful of pus. The tumor was stitched to the abdominal walls, and the greatest possible care taken to prevent the escape of any portion of the contents of the sac into the cavity of the abdomen. The back of the fœtus was turned uppermost, and in the process of extraction both the parietal bones dropped off. The cutaneous surface was almost entirely destroyed, and all the internal organs were found to be shrivelled up.

Hypodermic injections of whiskey were constantly kept up and the patient was alive at the conclusion of the operation, which lasted about half an hour, as it was performed with the most careful attention to every detail that would tend to bring about a successful result. The patient was placed in bed, and rallied fairly well, the sac was kept perfectly clean, and the temperature was normal now for the first time. For the first twenty-four hours there really seemed to be a little hope that the case would result favorably; but at the end of that time the patient began to grow rapidly worse. The pulse became very feeble, and the stomach refused to retain any food whatever. On account of the diarrhœa present it was impossible to employ rectal alimentation, and she died of starvation thirty-six hours after the operation.

The autopsy was performed by Dr. H. M. Biggs, who found the uterus in the rear of the tumor, and about the size of an ordinary virgin uterus. The Fallopian tube of the left side extended over to the sac, and its fibres were lost in the walls of the latter. This condition Dr. Lusk considered of great interest in connection with the history. The case was, no doubt, orginally one of tubal pregnancy. Later the tube burst, giving rise to the attacks of paroxysmal pain noticed; and the fœtus then developed in the abdominal cavity. He thought at first that the walls of the sac were composed of tissue identical with that of the uterus; but Dr. Biggs found, on examination, that this tissue was entirely fibrous. There was not the slightest sign of peritonitis, but the sac was so strongly adherent to the intestines that it required about half an hour to separate the adhesions at the autopsy. It was therefore evident that it would have been practically impossible to remove the tumor entire from the abdominal cavity.

This case, Dr. Lusk said, was chiefly interesting from the fact that the patient fell a victim to what he believed to be wholly erroneous teaching. All the authorities say that these tumors should not be removed until the health begins to decline. The danger was, that if the evidences of septicæmia were not distinctly recognized, operative interference was apt to be delayed until it was too late. One, at all events, of the four patients operated on by the Chicago gynæcologist referred to, as shown by the recorded history of the case, was in a dying condition at the time; and Dr. Lusk thought that if the other three were in the same exhausted state, there was no reason whatever to hope for any different results than those noted. The reason often given for delaying operative interference was, that in the course of time the fœtus would be very likely to be converted into a lithopædion; but statistics showed that the number of cases in which this occurs is relatively very small.

The presence of the fœtal tumor in the abdomen was always a source of constant pain and distress. As a matter of humanity, therefore, the child ought to be removed very soon after it has ceased to live; instead of being allowed to remain until the appearance of symptoms, which indicate that the constitution of the mother is already undermined. The cases which Dr. Lusk had investigated showed that nearly all the patients recover when the operation is undertaken at an early period. In itself it was not really a dangerous procedure, and the bad results which had been noted in so many instances were due simply to the fact that operative measures were adopted only as a last resort.

The development of the symptoms denoting putrid absorption was almost always insidious, and there were very few cases in which marked symptoms were presented until quite late in their history. The effect of the vicious process going on in the system was primarily in the blood, and afterwards resulted in the degeneration of all the parenchymatous organs. In the case detailed by Dr. Lusk the heart was especially affected.

Dr. Lewis Hall Sayre read a paper entitled:

A CONTRIBUTION TO THE ETIOLOGY OF POTT'S DISEASE.

The symptoms accompanying spondylitis in its earliest stages, he said, were vague, and not of a character to call attention directly to the spine. He was among those who look upon traumatism as the exciting and necessary cause, which in a constitution already vitiated need be much less severe to produce spinal or other lesions than in a person of vigorous health.

Later on in the paper he spoke particularly of the class of cases in which the disease commences on the sides of the bodies of the vertebræ, at the point of their articulation with the ribs, and not in the anterior part of the bodies, as is commonly the case. They were usually caused by some violence applied to the rib, which originated an inflammation at its articulating facet on the spinal column. These cases were more than ordinarily obscure in the commencement, and were difficult of diagnosis, as pressure on the head seldom caused pain, and the child could run, and sometimes jump without pain, and could often bend the body without inconvenience.

In order to detect this condition it was necessary to place the child across the lap, making strong pressure upon each rib, so as to bring it into firm contact with its articulating vertebræ; and when the rib was reached which articulated with the inflamed or diseased vertebræ, either pain would be produced or a muscular spasm, very similar to that caused by "point pressure" on a "contractured" tissue. Manifestations of trouble might also be produced by pressure made on either side of the spine over these articulations. In conclusion, he related a case illustrating this form of spondylitis.

Dr. Lewis A. Sayre remarked that the case described by his son was one of the most interesting that he had ever seen. It had been pronounced by a well-known neurologist to be one of organic disease of the cord, and there was absolutely no deformity that could be detected by the most careful examination. He himself thought there was no spondylitis until he made a lateral examination and found that pressure over the vertebral articulation with the eleventh rib caused acute pain. When this point of tenderness was discovered it became evident that there was disease at the side of the vertebra, and a plaster-of-Paris jacket was accordingly applied. Owing to the fact that the patient indulged in violent exercise before the latter was perfectly "set," it soon broke down and was removed at the end of two weeks, when a distinct knuckle was found. This proved that the diagnosis was correct; but if the first jacket had been perfect, it was doubtful whether any deformity whatever would have occurred, and the diagnosis of Pott's disease would have been open to question. The deformity, however, was now so slight that it would be likely to

entirely escape observation under ordinary circumstances.

After the narration, by the President, DR. C. A. LEALE, of a case of spondylitis occurring in a physician, Dr. J. W. S. GOULEY exhibited a peach-pit which he said was of interest as contributing a

CONTRIBUTION TO THE SUBJECT OF FOREIGN BODIES IN THE ALIMENTARY CANAL.

A gentleman seventy-one years of age had removed it from his rectum three months after it had been swallowed. It was an inch and a quarter in length, seven-eighths of an inch in breadth, and eleven-sixteenths of an inch in thickness. When it was extracted from the rectum the patient remembered that he had eaten some pickled peaches three months before, since which time he had not tasted any peaches. The case was interesting from the fact that the peach-pit caused no pain or distress whatever in passing through the intestinal canal. Dr. Gouley then related a case occurring in his service at Bellevue Hospital. In a patient suffering from delirium tremens, who died shortly after admission, there were certain heart symptoms which could not be satisfactorily explained, though there were some signs of pericarditis. At the autopsy the pericardium was found filled with flakey lymph, and when the heart was lifted up a metallic substance was felt. On opening the œsophagus this proved to be a plate with two teeth attached.

DR. GOULEY also mentioned a number of instances mostly taken from "Eve's Surgical Cases," in which enormous objects, such as forks, spoons, and egg-cups, were swallowed, and in some instances successfully passed through the body.

DR. LOUIS A. SAYRE referred to some interesting cases occurring in his own practice, and Dr. P. Brynberg Porter related a case recently reported by Dr. C. B. Hutchings, of California, in which an open penknife passed successfully through the alimentary canal, the patient, a young man of twenty, being advised to eat principally of such food as mush and buckwheat cakes, which would distend the bowels and prevent injury to them in the passage of the knife through the intestinal tract. Dr. Porter also spoke of a case recently reported to the New York Surgical Society by Dr. A. G. Gerster, in which a metallic button, three-quarters of an inch in diameter, was swallowed by an infant six months of age, without the mother's knowledge. On account of increasing dyspnœa and failing health, tracheotomy was performed six months later, under the supposition that the trouble was due to a laryngeal tumor; as at this time the button was firmly imbedded in the tissues between the œsophagus and the trachea, it was not discovered at the examination made immediately after the throat was opened, and three days afterward the infant died of pneumonia.

The President and Dr. E. S. F. Arnold also related interesting cases.

— At the approaching meeting of the British Association for the advancement of science, at Birmingham, commencing on September 1st, the organizing committee of Section A has arranged that a special discussion shall be held, jointly with Section D, on the physical and physiological theories of color-vision. The discussion will be opened by Lord Rayleigh, and Dr. Michael Foster will also take part in it.

SOCIETY OF MEDICAL JURISPRUDENCE AND STATE MEDICINE, NEW YORK.

STATED meeting June 10, 1886.

DR. E. C. SPITZKA read a paper on,

THE ATTITUDE OF LEGAL MEDICINE *versus* HYDROPHOBIA.

He did not believe, he said, that there was another branch of inquiry in which time-honored tradition, erroneous observation, ill-balanced reasoning, and immature theory played so large a part as in that relating to the transmission of rabies from animals to man. While his experience with spurious hydrophobia had been considerable, with the real disease it was infinitely small. Indeed, he would say *nil*, but that he wished to avoid discussing a question, both sides of which were represented by able thinkers and observers, namely: whether there is such a thing as genuine hydrophobia in man, due to transmission from lower animals, and to nothing else?

He then announced the following propositions as embracing the points maintained in the preliminary part of his paper:

(1) There is at present no epidemic of hydrophobia in New York city or its vicinity.

(2) A number of deaths have occurred from spurious hydrophobia (lyssophobia) in New York and its vicinity during the past nine months.

(3) The agitation of the subject of Pasteur's method of preventive inoculation for hydrophobia, and the accompanying strained accounts of suffering and death from that disease, are responsible for these deaths.

(4) To prevent the serious and oft-times fatal imaginary disease, it is necessary to inculcate a healthy public sentiment, which shall frown down the agitations of questions which are of a strictly scientific character by persons who are neither biologists or physicians, and who have no other motive than the creation of a sensation, regardless of consequences.

(5) It should be strictly inculcated on all officers intrusted with the preservation of the public peace and public health that the only way to determine whether a dog is suffering from rabies or no, is to submit him to the inspection by competent veterinarians in a living condition. The desirability of some such ordinance is attested by the fact that persons on the road to death by hydrophobia have recovered on learning that the dog which bit them remained alive and well.

(6) The results of researches on hydrophobia should, for the present, remain within the domains of technical literature. There are so many problems connected with the question of rabies which are as yet unsettled, and promise to remain so for some time to come, that it would be tantamount to criminal recklessness to publish prematurely alarming discoveries in the lay press.

(7) The method of demonstrating rabies by direct inoculation of the brain is fallacious. The conclusion drawn by Liantard, from an experiment thus performed, that the Riverdale dog was mad, was obtained by misleading methods.

(8) The means to be adopted to prevent future outbreak of spurious hydrophobia is to muzzle the dogs, to dam up within appropriate receptacles, the torrents of ink flowing from the pens of hasty investigators and to exclude sensational publications from the household.

Canine pathology would hereafter prove an easy science to master, since it would consist of but one

simple syllogism, namely: all symptoms of canine disease are symptoms of hydrophobia; all dogs presenting such symptoms should be destroyed; hence, for all such dogs there is but the remedy of the bullet or the policeman's club. Dr. Spitzka referred to the history of the so-called epidemic that prevailed since the "needless, wanton and wicked agitation of the matter which was begun a few months ago." For a week after the announcement was made relative to the Newark epidemic, several scores of cases of hydrophobia were reported from every part of the country; and he asked if a single case of the kind could be remembered in which any attempt meriting the adjective scientific — indeed, any attempt whatever, was made to verify the existence of the disease, and when it really was verified.

He then took up a number of the cases which he said had been published far and wide, with the deliberate and malicious purpose of causing a sensation; and stated that he would show that the result was the production of imaginary disease, real alarm, real suffering, and something else which was sufficiently real, namely death. In regard to the Newark cases he said: A dog had bitten a number of other dogs, as well as six children. The transgressor was killed, in accordance with the time-honored custom of hanging such criminals first, and then trying them afterwards. Four of the children were sent to Pasteur, and two remained in Newark, while the bitten dogs were very sensibly locked up where they could do no harm, but on the other hand, where it could be determined whether they had really been inoculated with hydrophobia or not. The result proved that they had not, and the two children who did not go to Paris remained as well as the others, showing that in this case, at least, the alarm had been a false one. In speaking of the case of George Neall, the Newark pound-keeper, he said that it seemed that for several days, that is, during the entire time of his illness, he obtained no drink, and ate nothing except an apple. Dr. Spitzka stated that it was evident that the man was under the dominion of a terrible fear from the fact that he got up shortly before his death, walked into the kitchen, placed his hand in a pail of water, and had a spasm in consequence, which lasted half an hour; and he then asked whether starvation, depressing neurotic remedies and terror were without an effect on this patient's vitality.

Animals, he said, were liable to become insane, as man did, from various causes and in various ways; and he had hoped to exhibit to-night an insane cat, the pet of a friend, which had been shot in the head. In Japan, as Professor Law informed us, the boys produced what was supposed to be rabies by administering a certain fungus to dogs. He believed the number of persons reported as dying of hydrophobia almost simultaneously with the agitation of the subject of Pasteur's methods, but who had been bitten between nine months and nine years before, would be found to amount to a hundred or more.

The ablest review which had yet been made of the subject of spurious hydrophobia, was by Dr. Dulles, of Philadelphia. He showed that this condition might result from (1) disorders of the stomach, especially in very young children, as well as from inflammation of the œsophagus and stomach in adults; (2) disorders of the respiratory apparatus; (3) disorders of the circulatory apparatus; (4) systemic conditions, such as rheumatic fever, uræmia, intermittent fever, mercurialization and pregnancy; (5) disorders of the nervous system: meningitis, pachy-meningitis, tumors and parasites of the brain, simple neuritis, acute mania, delirium, alcoholism, tetanus, hysteria, and neurotic poisoning. He then related three cases which he said he was able to add to the instances collected by Dr. Dulles, where symptoms commonly or erroneously regarded as hydrophobia were present. The first was one of epileptic delirium which he saw in consultation in Williamsburgh, and the report of which he had published in the *New York Medical Record*. The second was one of typhus fever which was sent to the Presbyterian Hospital, New York, and which on account of the character of the delirium present, was supposed to be one of hydrophobia. The third case, one of disseminated sclerosis, described by Pollak, he quoted from the *Archiv. für Psychiatrie*. Dr. Spitzka considered the resemblance between spurious hydrophobia and the so-called real affection so great that he could not criticize any one for believing, with Dulles, that the existence of a genuine hydrophobia in man was not proven; and by way of corroboration subjoined some extracts from an article in "Pepper's System of Medicine," the author of which was a believer in the reality of hydrophobia.

Later he referred to the fact that a "Pasteur Institute" had been organized in New York, and said that he believed he was doing that institution no injustice when he said that the more hydrophobia scare could be created in the community, the better it would flourish. It rested for the present on two foundations: First, on a rabbit brought over from Paris, which had been inoculated by Pasteur, and second, on the allegation that hydrophobia now existed in New York city. Inasmuch as one of the incorporators of the institute (Dr. Liantard) had contributed to the public alarm on this question, by the published autopsy on one dog, and an experiment on another, he proposed to present for consideration certain facts which he thought would not be gainsaid by any of his medical friends, and to bring before the Society some animals to which these observations related. The brains of one or two of these could be removed, and those present could examine both the living and the dead subjects; so that they could themselves test the correctness of his conclusions.

Dr. Spitzka then proceeded to quote from the report of the Morosini case prepared by Dr. Liantard for the *American Veterinarian Review*, as published in the *New York Herald*. Miss Morosini was bitten on April 14th. The dog was killed almost at once, and on the same day was sent to the Veterinary College. Dr. Bulkley (the attending physician in the case), requested that a post-mortem should be made as early as convenient, as it was a matter of the greatest importance. The post-mortem was begun without delay, and there were revealed important lesions; congestion of the fauces, empty condition of the intestinal tract, which was slightly congested, stomach containing one large bird feather, the kidneys somewhat congested, and the bladder empty and retracted, and somewhat congested. These symptoms were considered sufficient evidence, with the history of the case, to justify a diagnosis of rabies. A report to that effect was made to Dr. Bulkley, and it was urgently advised by Dr. Liantard that the injured young lady should go to Paris as early as possible, and place herself under M. Pasteur for treatment. Then it was

decided at once to try cerebral inoculation, as carried out by M. Pasteur, to confirm the diagnosis.

The brain and medulla of the dog having been carefully kept, another large dog was secured for inoculation on the following morning. After placing the dog under complete anæsthesia, the cranium was trephined a little on one side of the median line. The dura mater was then carefully divided, and a little of the medulla of the first dog placed over the cerebrum of the second. The edges were brought together by sutures protected by wadding and collodion, and the animal was placed in a secure kennel for observation. He recovered from the anæsthetic, ate well, and the wound healed slowly; presenting apparently nothing abnormal. On April 30th, however, the dog appeared to be more affectionate to those who were caring for him, and also to the house-surgeon who watched him. On May 1st, the sixteenth day after the inoculation, he showed the first symptom of dumb rabies, paralysis of the lower jaw. The mouth was slightly open, the jaw hung down, and abundant saliva flowed from the mouth. The next day the lower jaw became more paralyzed, and the animal was weak and tottered in his gait, while paraplegia now showed itself. The dog died on the 2d, and at the autopsy the following lesions were found: Pharynx highly congested and containing considerable foreign matter, such as hay and straw; the stomach also highly congested. In it were found the same foreign substances seen in the pharynx; the intestines were empty and the bladder empty and retracted.

So far as Dr. Liantard's diagnosis of rabies in the dog that bit Miss Morosini was concerned, Dr. Spitzka said that he had to state that as assistant to Prof. Henry Draper at the University of New York, he had had the opportunity of examining scores of dogs brought into the laboratory, and not one of them even showed any signs of rabies. On the contrary, they exhibited that docility and affection which, under the circumstances, was the most touching characteristic of the animal. There was scarcely one, and certainly not one young dog, in whose stomach he did not find more or less foreign material. This became a subject of comment in the laboratory, and it was supposed to be a satisfactory solution of the problem that intestinal worms were found in large numbers in those dogs which had the largest assortment of foreign bodies in their stomachs. The speaker referred to a cat which contained three tapeworms. The feather in the stomach of the dog which bit Miss Morosini, therefore, went for nothing. As to the congested kidneys, congested fauces and empty bladder, he would simply ask how the fauces, kidneys and bladder would appear of a man who had been hunted for several hours by a large crowd armed with shot-guns and pitch-forks.

With regard to the "dumb rabies" which Liantard thought he had produced in the second dog, every one familiar with the researches of Schiff, Flourens, Hitzig, Fritsch and Goltz, would recognize in it the ordinary results of experimental and inflammatory disturbance of the brain function in the dog. According as the irritating injection affected one cortical field, or another, the paralysis would vary; but paraplegia was quite characteristic of meningitis and encephalitis in the dog. In order to show that the symptoms of hydrophobia, as Dr. Liantard considered them, could be produced in healthy dogs by introducing non-rabic foreign substances into their skull cavities, he had performed experiments on six dogs, the details of which he now proceeded to present. In the first, the cranium was trephined May 29, and, after incision of the dura mater, six cubic millimetres of the spinal cord of a healthy calf, slaughtered about twenty-eight hours before, introduced into the brain substance. On June 2d, there was manifest paralysis of the hind legs, with considerable fever. The eyes were dull, and there was ptosis. The disposition of the animal was exceedingly friendly. The wound was granulating and discharging healthy pus. In the second dog, a mongrel spitz, on May 29, a button of bone was removed in the right temporal region, and some of the same material used in the last experiment was introduced in a comminuted form. On June 2d, it was noticed that there was some paralysis and ataxia of the hind legs. It showed a marked tendency to fawn, in the place of its naturally aggressive disposition.

The third dog, a large mongrel black-and-tan, was trephined June 2d, about an inch from the median line, and through the opening, twenty drops of an emulsion of a calf's cud was slowly injected by a hypodermic syringe into the brain. This was followed on June 5th by paralytic and ataxic symptoms, which were marked on the left side more than on the right. On June 2d, a fourth dog, a mongrel collie of vicious disposition, was operated on in the same way as the last, except that the material injected was an emulsion prepared from the pons and cerebellum of a patient who died of hydrophobia on May 14, whose brain he obtained through the courtesy of Dr. P. H. Kietschnar of Brooklyn. This was injected into the parietal region, and, by calculation, into the thalamo-aural region.

On June 6th, there was some doubt as to whether there was any weakness of the hind-quarters or not. At that date it was the liveliest of the four dogs, and fed best.

In the fifth dog a slit was made in the dura mater, after trephining, and a piece of common yellow soap of the size of fifteen cubic millimetres introduced between the dura and pia. In the sixth, ten drops of horse's stale urine were injected into the brain substance of the posterior region. This animal had a glandular and suppurating swelling in the inferior nuchal region.

Dr. Spitzka then put the following questions:

(1) Is there any symptom of hydrophobia related of Dr. Liantard's animal, which is not present in these dogs inoculated with the spinal cord of a calf, with soap and with decayed fluids?

(2) Are the mental disturbances resembling those of dumb rabies, so-called, not even much greater in the dogs exhibited to-night than appears in the account of Dr. Liantard's dog?

(3) Would it not have been well to have performed such experiments as those whose result is shown to-night at the same time, or before attempting to make of the inoculation of the brain a test of hydrophobia, and alarming the public?

(4) Was it wise, in view of the bad effect which the knowledge that the dog which bit a person was mad, has on that person's mind, to make this announcement in such a shape that it must reach him or her?

(5) What reason had Dr. Liantard or his house-surgeon for omitting an examination of the brain in the case cited, or, if they made it, for failing to publish its morbid appearances?

Dr. Spitzka said he had been thus lengthy in detailing the faulty nature of the evidence on which an epidemic of hydrophobia might be announced, and in demonstrating that mere terror and expectant attention were the chief factors in the spread of the disease, because the practical problem with which legal medicine had to deal, was not so much the prevention of a genuine, as of a more or less artificial disorder. Inasmuch as the same measures which would check the spread of the real disease, if it existed, would also, and as effectually, check the ravages of that terror-psychosis known as hydrophobia, we might deal with both together. The bite of any animal, or even of men, suffering from febrile disorders, excitement, tetanus, or blood-poisoning, was more or less dangerous; and undoubtedly many of the sequelæ of such bites had been summed up under the general caption of hydrophobia. Whatever theory we adopted, it was the duty of the community to protect its members not only against the more or less venomous bites of such animals, but against intrinsically harmless bites. Historically speaking, the system of muzzling dogs had been found so efficacious, that it was strange that it had not been universally adopted.

Having given some statistics on this subject, and stated that the plan of muzzling had been adopted in England, he remarked that everything, of course, depended on the manner in which the law was enforced. If, as was only too likely in our community, the persons entrusted with its execution were selected from the worst class of ruffians, and their pay were made dependent on the number of dogs they could steal from their owners, and the amount of blackmail they could buy through such acts, the public would become disgusted with the law, and those evading it would be supported, instead of condemned by public opinion. Another precaution which had been almost uniformly neglected on this side the Atlantic, was the proper observation of suspicious dogs. There was no evidence so good as that obtained from the living subject of rabies. In addition, much suffering and indeed, many deaths, might be prevented by the discovery that a dog which had bitten was not mad; and that could be determined with certainty only by keeping the animal alive.

With regard to the recognition of a Pasteur institute as a factor in the legal enactment of measures to prevent hydrophobia, he quoted the following passage from the *Deutsche Medizinische Wochenschrift* of April 29, 1886, which coincided entirely with his own opinion. "Attention has been repeatedly directed in this Journal to the fact that the method of Pasteur cannot be unreservedly accepted as an established one, and that the formation of Pasteur institutes is premature until the method of preventive inoculation be placed on an absolutely fixed basis, which, in view of the large number of experiments on animals and inoculations made daily in Pasteur's laboratory, will presumably be affected in a not unduly remote period. It were high time, indeed, that we left behind us the stage of newspaper reports, which for some months have furnished nothing new beyond the daily increasing number of those inoculated, and the deaths, and replaced the present monopolization of the matter by the coöperation and critical proof-tests of competent observers."

One of the dogs inoculated by Dr. Spitzka died the day before the meeting, and the autopsy revealed the presence of well-marked meningitis, while another, the bull-dog inoculated with a portion of the spinal cord of a calf, was despatched in the presence of the audience. The autopsy in this instance, which was made immediately after death by Dr. N. E. Brill, showed the animal to have been suffering from hæmorrhagic encephalitis.

DR. DULLES, of Philadelphia, expressed himself as extremely skeptical in regard to the existence of such a disease as true hydrophobia. If there were such an affection he thought that Dr. Spitzka had produced it with simple inoculations of matter not derived from rabid subjects. He believed that fifty years from now the specific theory of hydrophobia would have as few adherents as the doctrine of witchcraft had at the present day. Patients suffering from so-called hydrophobia might be divided into three classes:

(1) Those affected with a variety of diseases giving rise to symptoms of a similar character to those described as belonging to rabies, such as tetanus, for instance; (2) Those having certain affections of the mind, such as mania, and other forms of insanity; And, (3) those suffering simply from fright.

DR. BRILL read a short paper, the object of which was to throw discredit and ridicule upon Pasteur's work.

DR. KRETSCHNAR said, that however skeptical any one might previously have been, he thought that if he were called upon to treat a *bona fide* case of the disease, as he himself had recently been, he would be convinced that it had a very positive existence. In this instance he did not know that the patient had been bitten at all until within a few hours of his death, and supposed that the man was suffering from spasm of the glottis; while the patient himself was not at all the victim of fright, and at one time in the course of the attack, when he had been rendered comparatively comfortable by morphia, felt confident that he would recover.

DR. H. M. BIGGS, of the Carnegie Laboratory, said that while Pasteur had not, in his opinion, as yet positively demonstrated the correctness of his views, he thought that he had done enough to show that there was a strong probability of their being substantially true. Excluding the Russian patients, who had been bitten by wolves, there were but two cases out of over nine hundred, in which hydrophobia had occurred in those who had been inoculated after being bitten by animals supposed to be rabid; and there were certain circumstances connected with both of these which rendered them of such a character as not to invalidate the protective power of the inoculations under suitable conditions. Pasteur had devoted six years of arduous study to this subject, and if it were not hydrophobia that he was dealing with, it must be some new disease, the existence of which had been hitherto unknown, since there was no form of septicæmia which had an invariable period of incubation, this period being of definite duration in both dogs and rabbits, and being entirely different in the two kinds of animals.

As to the Newark children, while it had not been positively demonstrated that the dog which bit the children had true rabies, it seemed to him highly probable that it had, since it acted precisely in the manner described in the books as characteristic of rabid dogs. Thus, it ran for a distance of about three miles, snapping and biting at everything that came in its way.

He had learned on the highest authority that it was not known certainly whether the dogs which were kept under observation afterwards had really been bitten or not. At the end of two or three months, no symptoms of rabies having developed in any of them, they were all killed with the exception of one, which was returned to its owner; and it was a significant fact that ten days after it was released from confinement, it was seized with the characteristic symptoms of rabies, and died. While it was true that the two children which had remained at home were as well to-day as the four who were inoculated by Pasteur, he had positively ascertained that in the case of one of them there was only a very slight abrasion produced by the dog, and that in the other there was not even as much as this. The skin was entirely unbroken, as the boy was protected by a heavy overcoat, in addition to other winter clothing.

We had been called in consultation to see Neall, the keeper of the Newark dog-pound, who died a short time ago, of supposed rabies, and agreed with those in attendance that the case was probably a genuine one of the disease. The inoculations which he had made with specimens of the brain and spinal cord of this patient, had, however, proved entirely negative in their results; and therefore he was forced to the conclusion that a mistake in diagnosis had been made in this instance. As to the inoculations of dogs made by Dr. Spitzka, and described in his paper, the results obtained were of no value whatever, and he felt called upon to express his emphatic protest against the whole tone and drift of the proceedings this evening. In other fields Pasteur had done such admirable scientific work, and accomplished such splendid results, that he thought his present researches should not be condemned until they had received a more thorough investigation than it had as yet been possible to make in regard to them.

Recent Literature.

Transactions of the American Gynæcological Society. Volume X. for the year 1885. New York: D. Appleton & Co. 1886.

These volumes of transactions are always welcome, embodying as they do in so attractive a form so much that is of interest and value. The President, Dr. W. T. Howard's address presents "Two Rare Cases in Abdominal Surgery." The differential diagnosis in these cases is very thoroughly and instructively worked out, and the first one, a case of encysted tubercular peritonitis, as proved by the autopsy, is especially interesting because of its rarity.

Dr. Busey's paper on "The Natural Hygiene of Child-Bearing Life," contains a number of important truths, but they are unfortunately so obscurely stated that the reader loses much of their force. Fewer words, less involved sentences, and a simpler style would add to the value of the paper.

Dr. H. G. Garrigues contributes a paper on "Puerperal Diphtheria," whose special value lies in the fact that it very clearly points out that so-called puerperal fever really includes several different processes, and shows how the recognition of the real nature of any one form is quickly followed by appropriate treatment, and lowered mortality. Recognizing the diphtheritic character of the grayish patches which occur in a certain number of cases, it was a natural sequence to apply such a combination of general and local remedies, as to lower the mortality. Dr. Garrigues refers in this connection to the very elaborate antiseptic precautions which he observes in all cases of labor, and makes the gratifying statement that in two years from the introduction of such treatment, the mortality fell from 7.69 per cent. to less than three-quarters of one per cent.

Dr. J. T. Johnson's paper entitled: "Four Cases of Oöphorectomy with Remarks," adds but little to our knowledge of the subject. The discussion was almost exclusively on the question when the operation is justifiable. The general tone of the remarks was conservative, Dr. Emmet going so far as to say that he thought more harm than good had been done by the operation. He found no one to agree with him in such an extreme view, however.

Dr. Thad. A. Reamy gives a new method of supporting the perineum during labor, which will hardly, we think, prove of more value, than other well-known methods. Dr. E. W. Jenks reports an interesting case of Cæsarean section. Dr. Elwood Wilson in his "Remarks on the Use of Tarnier's Forceps," withdraws the protest he made in 1881 against their use, and gives the notes of nine cases in which they have proved of great service.

The value of Dr. Sutton's paper on "Emmet's Cervix Operation modified in Certain Cases," lies in the discussion. The paper starts the question, what should be done when there is so much hypertrophy of one or both lips, that even after denudation, the lips cannot be properly approximated. The author advocated a partial amputation, or carrying the denudation completely across the hypertrophied lip. Various other methods were proposed, the best in our judgment being that advocated by Drs. Skene and Baker of leaving the undenuded strip for the cervical canal, and cutting out a V-shaped piece on one or both sides, as may be needed.

"Inflammation of the Parotid Glands following Operations on the Female Genital Organs," is the title of a short paper by Dr. Goodell. His cases and numerous others cited in the discussion seem to prove that the parotitis is not a mere coincidence, but that some sympathetic relation exists between the sexual apparatus, and the parotid glands.

An ingenious paper follows, by Dr. Chadwick, on "Peristalsis of the Genital Tract, and a New Theory to Explain Relaxation of the Vaginal Outlet during Labor." The theory seems to us tenable and to explain in a very rational way phenomena which every physician must have observed. A paper on "Facial Paralysis of the New-born," by Dr. Theophilus Parvin, contains nothing new.

The longest article in the Transactions is that by Dr. H. F. Campbell, on "The Genu-pectoral Posture: its Value in Impeded Uterine Reduction, and in the Prolonged Nausea and Vomiting of Pregnancy," which is really a continuation and completion of his paper read before the same Society in 1876. When the fact is considered that there is practical unanimity in the profession as regards the great value of this posture in effecting uterine replacements, it may be questioned whether so prolonged a discussion is not unnecessary, and perhaps unprofitable. We are of the opinion that the simple entrance of air into the

vagina even in the perfect genu-pectoral position will often fail to reduce the uterus. Some pressure on the fundus through the posterior cul-de-sac, or some traction on the cervix will usually be necessary.

The position is a valuable aid undoubtedly, and even Simpson and Hart in their brochure allow that. We think the criticism which Dr. Campbell makes that their conclusions drawn from a cadaver placed in this position and frozen, are faulty, is perfectly just. The conditions are too different to be of value for purposes of comparison. This paper is of special importance from its emphasizing the rôle which uterine displacements undoubtedly play in causing nausea and vomiting of pregnancy, and the great help the genu-pectoral position is in their reduction.

Three interesting papers by candidates close the volume which on the whole can hardly be said to equal some of the others in the importance and originality of its contents.

On Asthma: Its Nature and Treatment. Containing an entirely new and comprehensive working hypothesis, suggestive of new remedies, and of the more efficient applications of old ones. Illustrated. By Horace Dobell, M.D., etc. London: Smith, Elder & Co. 1886. 4to. pp. 32.

Dr. Dobell tells us that for some years the subject of asthma has been much in his thoughts, and that in 1878 he began to query whether asthma is due to some interference with the ease with which the hæmoglobin combines with and also delivers up oxygen. Reflection and study led him to think that this query "may be made the basis of a more comprehensive working hypothesis than any other with which I am acquainted." We have at the present day a large number of theories as to the pathology of asthma, each of which may be more or less applicable to some cases, but no one of which can explain all that come under our observation. Dr. Dobell thinks that his hypothesis, starting from the hæmatin and hæmoglobin in the tissues and blood, and their relations to respiration and histogenesis, brings "those other hypotheses which have a rational *locus standi*, but which have hitherto been considered antagonistic, into possible or probable harmonious correlation."

It is impossible here to set forth the line of argument by which this hypothesis is supported, and it must be stated that the reasoning is not so clear as it might be. Even with the aid of the ingenious diagram at the end of the book, it is not always easy to follow the author. The book is suggestive of thought rather than replete with fact. One useful purpose, at least, which it will serve is in enforcing attention to the fact that an asthmatic paroxysm is but a symptom, a fact which writers sometimes seem to lose sight of. There must be some underlying cause for the occurrence of so marked and peculiar phenomena in such varied conditions as, among others, hypertropy and polypus of the nasal mucous membrane, emphysema, and chronic bronchitis, foci of disease in the lungs, heart or kidney disease, dyspepsia, certain diseases of the central nervous system — to say nothing of the purely nervous asthma, with no appreciable anatomical changes in any part of the body. It must be clearly understood that Dr. Dobell does not mean to assert that the constant factor is failure of the hæmoglobin to absorb or give up oxygen, but only suggests an hypothesis which he thinks may help explain all the facts.

One practical point deserves notice. A distinction must be made between the true paroxysm of asthma and its ghost, or the "phantom paroxysm." During the height of a bad attack, the respiratory centre calls upon the will for aid in respiration to avoid asphyxia, and the latter may continue to act after the period of necessity has passed, not realizing that the lower centres may again be safely trusted with the work. Under these circumstances, antispasmodics and narcotics are no longer useful, but stimulants to increase the heart power and excite the reflex respiratory centres by an increased afflux of fresh blood, are called for. A striking case in point is cited. A complete list of remedies for asthma is given, and it is suggested that the anhydrous oxide of barium is worthy of careful experimental test as a remedy by reason of its analogy to hæmoglobin in its behavior to oxygen. That barium and its soluble salts are poisonous contraindicates their use no more than that of arsenic, for instance. F. C. S.

The Surgical Diseases of Children. By Edmund Owen, M.B., F.R.C.S., Surgeon to the Hospital for Sick Children, etc. Philadelphia: Lea Brothers & Co. 1885. pp. 504.

This volume, which is one of the series of clinical manuals for practitioners and students of medicine, is written in a very attractive, interesting manner. It contains much important and valuable information concerning the affections of children requiring surgical aid, and is also filled with practical suggestions, a knowledge of which is of great service.

Pathology occupies apparently a secondary position in the arrangement of the work. The clinical history of the diseases treated often describes only typical cases.

Occasionally one reads portions of a subject with pleasure and admiration at the concise graphic statements of the author only to ultimately have the interest thus aroused left ungratified, so that one cannot help wishing the entire subject had been treated in the instructive practical way in which it is in part presented to the reader.

Treatment has especially received the author's attention. It contributes much to the value of the work, and is with some exceptions quite satisfactory. For example, the "simple" treatment recommended for genu valgum and "bow-legs" seems quite easy and attractive, but a short experience would probably demonstrate that the method was not as practical as its description would cause one to expect.

It is also disappointing to find the same old familiar cuts of apparatus, which are seen in almost every surgical work, recopied again without any allusion to the improved patterns which experience has developed. Thomas, for instance, has made several valuable changes in his knee-splint since he published in 1876 the figure of the apparatus subsequently so extensively copied.

As a manual to enable one to make a rapid review of a subject it will be a valuable addition to a surgeon's library, but as a "complete monograph" it is in certain respects disappointing.

Any one who has treated spinal caries with plaster-of-Paris cannot but admire the author's skill and manual dexterity which enable him with "the help of an able sister" to apply fifteen jackets in one and one-fourth hours.

Medical and Surgical Journal.

THURSDAY, JULY 15, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

283 WASHINGTON STREET, BOSTON, MASS.

MODERN VIEWS AS TO FUNCTIONS OF THE LIVER.[1]

EXPERIMENTS made by means of the biliary fistula have shown that the biliary acids, though resembling the fatty acids in their chemical composition, are not derived from the fat of the blood, as no more bile is secreted when the animals are fed on fat alone than during entire abstinence from food. On the other hand, Nasse has recently proved, as did the earlier experimenters, that a highly azotized diet occasions a great increase in the flow of bile, and the inference is a legitimate one that as far as the components of the bile are the products of food, it is from the so-called protein compounds that they are chiefly derived. Moreover, as fasting does not altogether arrest this secretion, it may be inferred that bile is also formed from such of the nitrogenized ingredients of the blood as come from tissue disintegretion.[2] The earlier physiologists took advantage of this fact to recommend as a therapeutic measure to "bilious" persons, whether their biliousness was supposed to be due to functional torpor of the liver, or to excessive bile production, — that they should lessen or suspend the ingestion of meat albuminoids.

Another fact learned from the biliary fistula is that the flow of bile is greatly augmented after the ingestion of food, while it is almost *nil* during abstinence.

We have here room for but a brief allusion to Rutherford's important experiments made to ascertain the activity of the biliary secretion after the administration of different medicinal substances. According to these experiments aloes is the best cholagogue, and laptandrin the poorest; calomel had hardly any action, such purgatives as podophyllin, iridin, euonymia, jalap, sulphate of soda and colchicum, proved to be excellent promoters of the biliary flow. It is not known whether these medicines act by stimulating directly the hepatic cells, or the secretory nerves, or both: there is reason to believe that they do not produce their cholagogue effect by causing congestion of the liver.

Important knowledge has been obtained concerning the functions of the liver by comparing the blood which leaves the liver by the hepatic vein with that which enters it by the venæ portæ. Thus Claude Bernard proved that fibrin is destroyed or transformed in the liver, and the analogy of chemical composition renders it extremely probable that effete fibrin is utilized in the liver for the formation of the resinuous acids of the bile. Certain it is that the blood of the hepatic vein contains little or no fibrin, and similar observations with regard to the red blood corpuscles have led Murchison to conclude that the liver "is the grave of the red globules." The similarity of composition of hæmatine and bilirubin has also made it probable that the nitrogenous coloring matters of the bile are the result of this destructive process.

As for urea and uric acid, Cyon has remarked a large increase of these principles in the blood of the hepatic over that of the portal vein. It has, moreover, been proved by Murchison, Charcot, and Brouardel, that all congestive affections of the liver augment the quantity of urea in the urine, while in all destructive diseases of that gland urea-excretion diminishes notably. The conclusion of these physiologists is that urea is formed in the liver, the quantity of its production being dependent on the integrity of the hepatic cells and the activity of the hepatic circulation, and Murchison finds evidence of a pathological order that the liver is the main source of uric acid production.

The views which point to the liver as the organ where effete nitrogenous principles are elaborated for elimination by the kidneys in the form of urea and uric acid (and the frequent occurrence in this gland of inosite, hypoxanthin, leucin and tyrosin indicate an influence of the liver in the formation of other effete nitrogenous elements), views, moreover, which make of lithiasis and lithæmia a hepatic affection, have profoundly modified the therapeutics of the present day, both from a dietetic and medicinal standpoint.

That the liver, moreover, has to do with the elaboration of peptones absorbed from the digestive canal seems also evident, as Fothergill has intimated, from the mal-nutrition which follows hepatic disturbances. According to Albertoni and Schmidt-Mulheim, the peptones when escaping into the general circulation are depressant agents "producing alarming, if not dangerous symptoms"; "these peptones normally disappear from the portal blood before it reaches the general circulation," a proof that some important change in their composition is effected in the liver.

That the liver has the remarkable property of destroying certain toxic principles — animal and vegetable poisons — has also been determined by recent observations. Claude Bernard was the first to notice the innocuousness of certain poisons — as curare — in-

[1] Continued from page 19.

[2] How the liver forms bile is unknown. If the bile acids are products of food proteids, or effete fibrin, the cholesterine would seem to be performed in the nervous system, being simply separated in the hepatic cells with the bile. It is probable that but little of the bile secreted is eliminated as such, being reabsorbed into the blood and there undergoing metabolism into less complex products which are eliminated by the lungs and kidneys. The cholesterine and bile pigment are excrementitious, and in passing out through the intestinal canal stimulate peristalsis and arrest decomposition.

troduced by the mouth, the toxic agent being rendered inert in the liver, and the effects of certain solanum alkaloids, as atropine and duboisin are retarded and minimized by the action thereon of the hepatic cells, which also, as is well known, have the property of fixing the salts of arsenic, lead and copper, and eliminating them in part in the bile. In other words, "the liver is a huge filter allowing certain nutritive matters to pass onward, while arresting other matters whose presence in the blood is deleterious." (Fothergill.)

For ages, as before said, the principal function of the liver was supposed to be the formation of bile, which, from being regarded as merely excrementitious, came afterwards to be considered a digestive fluid second only in usefulness to the gastric juice. The importance of bile as a digestive fluid has certainly been overrated, as it has been proved that digestion and assimilation are possible without it, but the facts concerning the uses of bile,— such as they are,— in the alimentary canal, (neutralizing and rendering aseptic the chyme, precipitating peptones, promoting the absorption of fats, stimulating intestinal peristalsis) were known to physiologists in the earlier part of this century. It is not so with the discovery of the glycogenic function of the liver by Claude Bernard, which dates from the years 1849–1851.

As the liver detains, modifies and elaborates the products of the digestion of azotized aliments (proteids), it does the same with the glucose elements which result from the digestion of starches and sugars; nay, more, it also forms out of albumen and fibrin, a sweet principle which it stores away in its cells, reserving it for the wants of the economy, to be either burned for the production of animal heat, or to subserve some, as yet, unexplained purpose in histogenesis. To this saccharine principle which, under the influence of contact with a peculiar animal ferment formed in the liver passes to the state of liver sugar, ($C^{12}H^{12}O^{12}$ 2 H^2O), Bernard gave the name of glycogen. Excess in the production of this sugar by the liver, or failure in its oxidation and destruction in the tissues of the economy, constitutes diabetes.

This whole question of the glycogenic function of the liver, though one of the greatest interest, is still involved in obscurity. That liver-sugar is less histogenetic than calorifacient is an inference from well recognized physiological principles. If it be chiefly as fuel for the tissues that glycogen is stored away in the liver, then Galen's view that the liver is the centre of animal heat, is not far from correct.[3] If, moreover, the liver elaborates blood materials — as the foregoing considerations seem to teach — then Galen was right in assigning to this organ a hæmatopoietic function.

In another and final number we purpose to discuss functional derangements of the liver.

[3] Pavy's exhaustive experiments go to show that this substance, which may be constituted by a splitting up of albuminoids as well as by the metabolism of hydro-carbons, is a readily oxydizable agent, subserving muscular action as well as animal calorification, and probably also promoting cell growth.

IS MEDICINE A PROGRESSIVE SCIENCE?

Under this head, Dr. Morell Mackenzie discusses, in the *Fortnightly Review* for June, a question of the greatest importance. A point, he says, meets us at the outset, whether medicine is, strictly speaking, a science at all. Although the elementary principles of physiology are as certain as any other scientific truths, the practical application of them in the treatment of disease can hardly ever possess more than a higher or lower degree of probability. The diagnosis of a case of organic disease of the heart, for example, cannot, during the patient's life, be treated as a verity of the same order as the circulation of the blood. The final test of a science is the possibility of predicting the phenomena belonging to its domain. Here the incompleteness of medical science is conspicuous. The physician can never know beforehand the precise effect which a drug will produce in a given case, or whether a particular complication will occur in the course of a familiar fever. The science of medicine may almost be said to be limited to the class of truths which adorned the mind of the natural philosopher commended by Touchstone. We know that the property of rain is to wet, and of fire to burn, and we are sure that if a man's heart stops, or if he ceases to breathe, he dies; outside the circle of such fundamental truths, we are in the realm of mere probability. Nor is there much likelihood, Dr. Mackenzie thinks, that medicine will ever take rank among the exact sciences. The problems of life are too complex to be solved by physical methods, and all other means of investigation from their very nature offer only a more or less close approximation to accuracy of result.

With all its inevitable limitations, medicine, has progressed, and will continue to progress, slowly perhaps, and too often wandering from the right path, occasionally even losing ground. The difference between the past and the present is immense. A hundred years ago, the question, Is medicine a progressive science? might almost have been answered in the negative. The science was pretty much where Harvey had left it more than a century before, while the practice was little better than that of Celsus or Galen. The science of physical diagnosis by auscultation and percussion had not been discovered, and the recognition of diseases of the heart and lungs was to the last degree conjectural, whilst, as regards other internal affections, it was the merest guess-work. Tumors were arranged in a few hap-hazard groups, surgical operations were performed without any anæsthetics; compound fractures almost necessarily involved the loss of the limb; sufferers from calculus could only obtain relief by one of the most dreadful cutting operations of surgery; ignorance of the laws of hygiene made hospitals and jails but little better than pest-houses, and the mortality from preventable diseases defied all computation.

Contrast this with the medicine of to-day. The stethoscope has made it as easy to detect a damaged heart or an inefficient lung as a broken leg. The ophthalmoscope enables us to explore the innermost

recesses of the eye, while with the laryngoscope we can have ocular proof of the condition of the windpipe. The microscope enlightens us as to the true nature of morbid growths, and such timely information often makes it possible to check their development. Anæsthetics have robbed surgery of half its terrors and half its danger. The introduction of the antiseptic method has largely increased the percentage of recoveries after severe wounds and mutilations, and has also done much to insure the safety of the lying-in-chamber. Litholopaxy has taken the place of the operation of cutting for stone. Small-pox is no longer the scourge which it once was; typhoid fever still claims many victims, though it is being gradually driven off the field by an enlightened hygiene; typhus is almost unknown, except in the lowest and most squalid haunts of poverty. Madness is now treated as a bodily disease, not as the curse of God or the spite of the devil. The active principles of the most important medicines have been separated, so that the agent can be administered in a purer and more efficient form, while the physiological action of the drug is determined by experiment, and is taken as the index of the therapeutic value. Less physic is given, and it is prescribed with a clearer purpose. Better still, more attention is paid to the diet and the hygienic surroundings of the patient, and the knowledge of the natural evolution of diseases has resulted in a judicious reserve in the use of powerful medications. The doctrine of the bacterial origin of contagious diseases has given rise to systems of prevention whose success leads to the hope that the specific fevers, and even consumption, syphilis, and cancer may yet be banished from among men.

Having shown that the art of healing has made very decided progress, the question remains: Will it continue to advance? The answer must be emphatically in the affirmative. Medicine has the threefold function of curing, preventing, and alleviating human suffering. As regards the first, we have made comparatively little headway, but if we do not cure more, we at any rate "kill less," and that of itself is a great deal. It is not probable that (as Prof. Huxley thinks), a remedy for nearly all forms of disease will sooner or later be found in drugs. Means of preventing should be sought for, rather than specific antidotes, which have seldom been discovered except by accident, and which often fail in time of need. Much progress has already been made in the prevention of disease, and it cannot be doubted that in this direction lies the way for medicine to follow if it is to be truly progressive. Apart, however, from either cure or prevention, there is a vast field for the power of medicine to display itself. The veriest sceptic who has ever been ill himself or witnessed sickness in others, must confess that the physician can allay pain, ward off danger, soothe apprehension, and infuse hope. Even when the issue is fatal, is it to be counted as nothing that death, although victorious, has been disarmed of its sting of physical anguish? It may be boldly asserted that if medicine never wrested a single life from an untimely grave, it would still deserve supremely well of humanity for its power of relieving pain. In nothing is the progressive character of the healing art more conspicuous than in the constant additions which are made to our means of dealing with troublesome symptoms, which even if they do not threaten life, make it miserable and perhaps useless. If it be the destiny of mankind to have disease always going about among them, seeking whom it may devour, it is still much that more and better safeguards should be found against it; that its ravages should be lessened; and that our life, into which, brief as it is, such an amount of suffering may be compressed, should be rendered less and less subject to pain, and freer from bodily discomfort. On this ground alone medicine may well take its stand as a progressive science.

Other points touched upon by Dr. Mackenzie are: the increasing zeal for research, and especially for original investigation; the growing *esprit de corps* among physicians the world over; the coöperative methods in vogue, such as the collective investigation of diseases and remedies; and the wonderful diffusion of knowledge by medical societies (which are becoming more and more cosmopolitan), and especially by the medical press, which never had such power and influence as now.

MEDICAL NOTES.

— Dr. Brown-Séquard was elected member of the Paris Academy of Sciences in the section of medicine and surgery at its last meeting. He was admitted by a large majority, although his competitors included such men as Bouchard, Germain-Sée, Jaccoud, Hayem and Richet.

— The *British Medical Journal* records the following case of spontaneous transformation of morphine into apomorphine: A solution of hydrochlorate of morphine for subcutaneous injection (3 per cent.) was ordered for a patient, and its injection was promptly followed by relief of the pain, without any gastric symptoms whatever. Eleven months later the patient made use of the same solution, but this time the injections gave rise immediately to violent and uncontrollable vomiting. The solution was given to a well-known analyst at Paris for examination, and he ascertained that apomorphine was present, thus accounting for the sickness. He recommended, in consequence, that solutions of the salts of morphine should never be kept longer than four weeks, and that freshly prepared solutions should not be mixed with the old.

— Given a spacious theatre, crowded during an evening performance for a period of hours, what is the difference of the effects on its atmosphere produced by the electric light or by gas, particularly as to the temperature and the generating of carbonic acid? This problem Dr. P. Renk, Professor of Hygiene at Munich, has just set himself to solve. Taking the

Theatre Royal of that city, which is lighted by 1,400 lamps on the Edison system, he tested the two kinds of illuminants, with the following results: During a representation which lasted from 5.30 P.M. to 10.15 P.M., and which was witnessed by 1790 people, he found that while the rise in temperature in the pit was 11.1° Centigrade with gas, it was only 7.7°, also Centigrade, with the electric light; and that in the upper gallery it was 10.7° with the former, and not more than 7.4° with the latter. As to the increase in the production of carbonic acid, the results were equally important. In the pit it was as 2176 with gas to 1221 with the electric light, and in the upper gallery as 2855 with the first to 1430 only with the second.

— It is said that the average price of drugs has fallen, within the last three years, fully one-third. In some special instances, the cause for the decline is apparent; in others, authorities differ. In the case of quinine, there has been a reduction from $3 in 1880 to 52 cents at present. In opium, the course of prices has been similar, the ruling quotation of 1880 being $4.75 a pound, against $1.75 to-day. In the case of quinine, the supply has been vastly increased of late years by the cultivation of the cinchona tree in Ceylon and Java, and the production of a richer bark; a bark yielding two per cent. was formerly considered merchantable, whereas the present average yield is more than double that. The production has doubled, while the demand has remained the same. The present price returns so poor a profit to the growers of the bark, that many plantations have been destroyed during the last year to make way for tea or other culture. Quinine, moreover, was some time since, by a change in the tariff law, put on the free list, while opium remains subject to duty. Opium varies in price according to the stringency of laws against its importation or use in various countries, the American market being at present so over-stocked that a lot was recently sold at less than $1.75 a pound which cost $4 not more than a year ago.

— The President is having an opportunity to brush up his medical knowledge in connection with the special pension bills, of which he has received so many, and which he seems inclined to scrutinize so closely. In a batch of twenty vetoes which he returned at one time last week, for instance, was the case of one man who filed his declaration for a pension in 1884, alleging that he contracted chronic diarrhœa in the Black Hawk War. The records show that he served from April 18, 1832, to May 28, 1832. In vetoing the bill for his relief, the President says: "I am inclined to think it would have been a fortunate thing if, in this case, it could have been demonstrated that a man could have thrived so well with the chronic diarrhœa for fifty-four years, as its existence in the case of this good old gentleman would prove. We should then, perhaps, have less of it in claims for pensions. The fact is, in this case, there is no disability which can be traced to the forty days's military service of fifty-four years ago, and I think little, if any more infirmity than is usually found in men of the age of the claimant." In vetoing the bill granting a pension to another man, who claims that he contracted blindness, the result of rheumatism incurred in the service, the President says that there seems to be no testimony showing the soldier's condition from the time of his discharge to 1880, a period of fifteen years. The President continues: "After nineteen years had elapsed since his discharge from the army, a pension is claimed for him, upon a very shadowy allegation of the incurrence of rheumatism while in the service, coupled with the startling proposition that this rheumatism resulted just previous to his application in blindness. Upon medical examination, it appeared that his blindness was caused by amaurosis, which is generally accepted as an affection of the optic nerve. I am satisfied that a fair examination of the facts in this case justifies the statement that the bill under consideration can rest only upon the grounds that aid should be furnished to this ex-soldier because he served in the army, and because he, a long time thereafter, became blind, disabled, and dependent." Considering that five hundred and sixty-five of these special pension acts have been signed, and only ninety vetoed, it cannot be said the President's attitude is hostile to the veterans of the war. It is, however, critical, as when he points out that the wound for which one man asked compensation was received while on a private pillaging expedition in North Carolina, when he was hunted down by the Home Guards.

NEW YORK.

— Fourteen cases of small-pox have been discovered in Williamsburgh within the past fortnight, all of which were traced to a young Polish immigrant who landed at Castle Garden a short time since.

— During the past week a young son of Dr. W. H. Newell, of Jersey City, who was bitten some weeks ago by a dog supposed to be rabid, has been undergoing inoculations by the Pasteur method at the Carnegie Laboratory, at the hands of Dr. Valentine Mott, who has been propagating virus derived originally from the rabbit inoculated by Pasteur, which he brought from Paris in May. Very little money has, as yet, been subscribed for the support of a Pasteur Institute in New York, and it seems probable that the project will be abandoned, at least for the present.

—The recent intense heat has produced a marked increase in the mortality of the city. During the twenty-four hours, ending at noon, July 17th, 178 deaths were reported to the Health Department, 64 per cent. of which were among children under five years of age. During the succeeding twenty-four hours 169 deaths reported, of which 125 were of children under five. The corps of visiting physicians for summer work among the tenement-house population, which have for a number of years done excellent work in diminishing the rate of infant mortality during the hot weather, have not been appointed this season, as the Board of Estimate and Apportionment failed to make

any appropriation for the purpose, and the regular funds of the Board of Health are not sufficient to include the extra expenditure involved.

As a consequence the physicians of the "Sick Children's Mission" of the Children's Aid Society, which has for a considerable period carried on an independent work among the poor, finds a large increase in the demands made upon it, and it has been found necessary to employ additional physicians to visit the crowded tenement quarters of the east side. The system of medical aid is so arranged that a physician reaches the bedside of a sick child in any part of the city below Central Park, within an hour from the time that the case is reported at the headquarters of the Mission. A sanitarium for sick children is also conducted by the Society at Coney Island.

Miscellany.

THE AUTOPSY OF KING LOUIS OF BAVARIA.

THE post-mortem examination of the late king of Bavaria, made by Professor Rudinger, was confirmatory of the view expressed by the alienists as to his mental condition, and of their unfavorable prognosis. Extensive degenerative changes were found in the skull, the brain and its membranes consisting in part of abnormal development, partly of chronic inflammations of old and recent date. The scalp was thick and very vascular. The skull was small in proportion to the size of the body, and somewhat asymmetrical, the diagonal diameter from the left of the forehead to the right of the occiput being 17.2 centimètres, and from right of the forehead to the left of the occiput 17.9 centimètres. The roof of the skull was extraordinary thin, its greatest thickness being three millimètres (0.12 inch). The coronal and sagittal sutures were completely obliterated on the inside of the skull. On the inner surface of the frontal bone, on both sides, were a number of large and small bony growths. The superior longitudinal sinus was excessively wide behind and remarkably narrow in front, near the ethmoid bone. Groups of Pacchionian granulations projected into the interior of the sinus. The dura mater was generally much thickened; in the frontal region especially it was vascular and externally shaggy; a bony growth, two millimètres in height, was found here. The left petrous bone showed a projection a centimètre in diameter at the base, corresponding to a depression in the temporal lobe of the cerebrum. The sella Turcica was asymmetrically thickened, porous and fragile in a great part of its extent, as was also the anterior fossa of the base of the skull. All the sinuses in the base of the skull were filled with dark fluid blood. The brain (without the dura mater) weighed 1349 grammes (47½ ounces). The arachnoid, over a great part of both hemispheres, was thickened, and had a turbid white appearance. Over the median end of the left anterior central convolution, and the beginning of the first frontal convolution, the arachnoid and pia mater were adherent over a space of the size of a shilling, and formed a thick hard mass, by the pressure of which the corresponding part of the skull was reduced to the thinness of paper. On the surface of the skull, pretty equally on both sides, portions of the convolutions appeared shrivelled, especially the commencing parts of the three frontal convolutions, the middle end of the anterior central convolution, and the parts surrounding the middle division of the postcentral furrow. The substance of the brain was vascular and rather soft. The heart and lungs were healthy. There was chronic catarrh of the stomach. The liver was congested; the spleen was enlarged; and the kidneys were large, but normal. The body was 6 ft. 3 inches in length, and the circumference of the skull 40 inches.

AN UNUSUAL CASE OF EXTRA-UTERINE PREGNANCY.

A CASE of suspected extra-uterine pregnancy was recently reported by Dr. Blackwood, in the *Philadelphia Medical Bulletin*. The patient, whose age is not stated, was the mother of two children. In December, 1883, she had an attack of menorrhagia, which was treated by faradism of the uterus, and she menstruated normally early in January, 1884. She had connection on January 8th, for the first and only time since early in December. The intra-uterine treatment, by means of caustic applications, was resumed on January 15th. Early in February, severe abdominal pains were complained of, and relieved by morphine. The uterine applications were discontinued, as the Fallopian tubes on either side were perceptibly dilated. Since menstruation, ten applications had been made to the interior of the uterus, which, Dr. Blackwood affirms, was empty. Signs of impregnation, however, showed themselves, although no trace of the fœtus could be discovered. By the middle of March, a globular mass, of the size of a large walnut, was detected above the right groin. The tumor was very mobile, not tender, and was diagnosed to be a tubal pregnancy. Electricity was employed up to fifty-nine volts, with the object of arresting the development of the fœtus. In the course of a few days, the mass disappeared, and the patient became very weak and prostrate. A fortnight later, the tumor could again be detected, but was more central in position. The sound apparently showed the womb to be empty, and it could be drawn away to the left, and separated completely from the tumor. Dr. Blackwood was naturally very anxious about the case. By the end of April, the fœtus, which had been coming gradually nearer the uterus, had entered its cavity, and the internal os had closed. Ultimately, normal labor took place in the following December, fully six weeks beyond term, without complications during or after. Dr. Blackwood suggests that the delay in development may have been attributable to the employment of electricity, but he is quite at a loss to explain the other curious features of the case.

THE CARE AND DISPOSAL OF THE DEAD.

THE *Sanitary Engineer*, while inclined to favor cremation, does not think it necessary that there should be any restriction upon the liberty of the individual in this regard. It says:

"The great argument used by the advocates of this last idea is that earth-burial is dangerous to the public

health because of the air and water pollution which it produces, and especially, because it may thus be the means of the transmission of the germs of contagious disease. The effects of cemeteries upon the health of those living in their vicinity has been extensively and carefully investigated by competent inquirers in recent years, and the result is that there is no evidence as to the production or spread of disease from such a source. Of these investigations, one of the most interesting was that made in Saxony to determine the changes which occur in bodies buried in the ordinary way, and the results of which were reported by Dr. V. Rheinhard in 1882. A number of bodies which had been buried for different lengths of time were disinterred, and their condition carefully noted. This was done for various kinds of sepulchres, and for the rich as well as the poor. It was found that in all soils the soft parts of the adult human body are completely destroyed in seven years, and that, as a rule, fœtor disappears in three months, unless the body has been placed in an air and water tight burial-case. The clothing resists changes longer than the corpses. No proof was found that the health of those dwelling near churchyards was thereby injured.

The chief danger to health from suburban cemeteries is from the pollution of subsoil water which they may occasion. The amount of this danger depends in part on the geological structure and surface topography of the ground, and the direction of flow of the subsoil water, and in part on the distance of wells or springs from the cemetery.

In attempts to protect or promote the public health, it is wise, as a rule, to deal first with those dangers which are the greatest, the most obvious, and the easiest remedied, and not to run the risk of wasting force for want of concentration of effort. The dangers to health which are connected with the dead are chiefly connected with the mode of caring for the body prior to its interment; in comparison with these the dangers due to cemeteries are comparatively insignificant. The spread of contagion by funerals, the keeping of a dead body for several days in the house, and, in the case of the poorer classes, in the living rooms of the family — these are the first things to be guarded against.

The most urgent need in our large cities is for small mortuary houses located in or near the centres of the tenement-house and poorer population, to which houses the body can be taken immediately after death, and be properly cared for, instead of being left in the bedroom of the family.

None but those who have themselves seen what occurs when a death takes place in a family occupying two rooms in a tenement-house can appreciate the diminution of suffering and of danger to the public health which a few well-located and properly-managed houses for the reception and care of the dead would cause in a crowded city.

REPORTED MORTALITY FOR THE WEEK ENDING JULY 3, 1886.

Deaths reported 2,079: under five years of age 970: principal infectious diseases (small-pox, measles, diphtheria, and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 550, diarrhœal diseases 337, consumption 267, lung diseases 118, diphtheria and croup 87, malarial fever 24, scarlet fever 24, measles 20, whooping-cough 19, typhoid fever 15, cerebro-spinal meningitis 12, puerperal fever seven, erysipelas four, small-pox New York) one. From scarlet fever, Brooklyn nine, Pittsburgh eight, New York four, Cincinnati, Providence and Salem one each. From measles, New York nine, Pittsburgh three, Brooklyn, Baltimore, and Charleston two each, Cincinnati and District of Columbia, one each. From whooping-cough, New York nine, Brooklyn five, Pittsburgh two, Boston, Baltimore and District of Columbia one each. From typhoid fever, Baltimore four, New York and New Orleans three each, Boston two, District of Columbia, Pittsburgh and Fall River one each. From cerebro-spinal meningitis, New York five, Fall River three, District of Columbia two, New Orleans and Worcester one each. From puerperal fever, New York two, Brooklyn, Boston, Baltimore, Cincinnati and District of Columbia one each. From erysipelas, New York two, Cincinnati and Worcester one each.

In 15 cities and greater towns of Massachusetts, with a population of 800,772 (population of the State 1,941,465), the total death-rate for the week was 18.76 against 18.02 and 15.49 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending June 26th the death-rate was 17.0. Deaths reported 2,857: infants under one year of age 746; acute diseases of the respiratory organs (London) 194; measles 96, diarrhœa 83, whooping-cough 56, fever 32, scarlet fever 24, diphtheria 21.

The death-rates ranged from 12.4 in Cardiff to 37.1 in Preston; Birmingham 16.0; Bradford 16.6; Hull 14.4; Leeds 19.1; Leicester 13.8; Liverpool 18.0; London 15.4; Manchester 20.5; Newcastle-on-Tyne 20.9; Nottingham 18.7; Sheffield 12.9.

In Edinburgh 20.9; Glasgow 22.6; Dublin 24.7.

For the week ending June 19th, in the Swiss towns, there were 36 deaths from consumption, lung diseases 14, diarrhœal diseases 14, measles eight, small-pox two, diphtheria and croup two, scarlet fever, whooping-cough and erysipelas each one.

The death-rates were: at Zurich 11.5; Geneva 12.1; Basle 12.6; Berne 17.1.

The meteorological record for week ending July 3, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

SOCIETY NOTICE.

NEW YORK STATE MEDICAL ASSOCIATION. FIFTH DISTRICT BRANCH. Preliminary Notice.— The second annual meeting of the Fifth District Branch will be held in Brooklyn, on Tuesday, October 12th, 1886. There will be a morning and afternoon session. All Fellows are solicited to contribute to the meeting, either by reading papers, notes or communications, or by exhibiting specimens. The Secretary desires to be notified of the title of any paper to be offered as early as convenient.

J. G. PORTEOUS, M.D., *President.*

E. H. SQUIBB, M.D., *Secretary.*
P. O. Box 94, Brooklyn.

BOOKS AND PAMPHLETS RECEIVED.

Medical and Surgical Directory of the United States, comprising List of Physicians and Surgeons. Arranged by States with School practiced, Post-Office Address, Population and Location, Date and College of Graduation, Medical Colleges, Hospitals, Sanitariums, Asylums, etc. R. L. Polk & Co., Publishers. Tribune Building, Detroit, Michigan, and Elsewhere.

Anæsthesia. Who made and developed this Great Discovery? A Statement "Delivered upon the Mellowing of Occasion," by G. Q. Colton. New York: A. G. Sherwood & Co. 1886.

An Introduction to General Pathology, Founded on Three Lectures delivered at the Royal College of Surgeons, London, 1886. By John Bland Sutton, F.R.C.S., etc. Philadelphia: P. Blakiston, Son & Co. 1886.

Dermatologische Studien. Zweites Heft. Iethyol und Resorcin als Repräsentanten der Gruppe reduzicrender Heilmittel von Dr. P. G. Unna. Hamburg und Leipzig. Verlag von Leopold Voss. 1886.

The Modern Treatment of Stone in the Bladder by Litholapaxy. A description of the operation and instruments, with cases illustrative of the difficulties and complications met with. By P. J. Freyer, M.A., M.D., M.Ch. London: J. & A. Churchill. 1886.

ALBUMINURIC RETINITIS.[1]

BY JOHN G. BLAKE, M.D.

RENAL complications in pregnancy are always causes of anxiety to the physician. The uncertainties and probabilities are ever in mind, and the satisfactory termination of the case is a relief which most of us have had the pleasure of experiencing at one time or another. When vision is affected and the case becomes one of threatened blindness unless premature delivery or abortion is resorted to, there arises a grave question of judgment as to the respective rights of mother and child. The proper discussion of the question belongs rather to the oculist than to the obstetrician, and it is with the hope of having a little light shed on a subject where patient and physician alike are blind, that I venture to report the following case seen in consultation.

Mrs. W., twenty-six years, when six months pregnant with her first child, noticed that her sight was becoming impaired. She had not suffered from any of the common discomforts of early pregnancy nor was she now otherwise affected: neither was there marked swelling of the feet or face, pain in the back, head, vomiting or marked diminution of urine.

Her physician, after a brief course of treatment, referred her to an oculist connected with one of our public charities. A careful examination of the eyes revealed loss of vision to the extent of fifty per cent., and an analysis of the urine showed a small amount of albumen and some granular casts. Premature labor was strongly advised as soon as the child became viable, and abortion at any time that the sight became worse or the patient blind. Hæmorrhage into the macula was described to be the condition causing loss of sight, with the possibility, and indeed, strong probability, of its increase if pregnancy was allowed to continue to full term. The case went on for some weeks until the seventh month was reached, when I was requested to see it with reference to the advisability of inducing premature labor. I found a fair-sized, rather slight woman, in quite good health, showing externally no signs of albuminuria except perhaps more or less sallowness about the face, but no œdema, either of face or lower extremities; neither was she suffering from headaches, vomiting, or pains in the back; her vision continued about the same as when she visited the oculist, and showed neither improvement nor retrogression. I had the urine carefully examined with the result of finding only a small amount of albumen, and a few granular and fatty casts. Considering the circumstances of the case, that the sight had not grown worse, that the induction of premature labor was a pretty serious operation, that we could watch the case constantly and could interfere at any time the symptoms would justify, I advised against an operation. Nothing occurred during the remaining period until the completion of pregnancy. Labor began at 9 P.M., progressed favorably through the night, and was completed with forceps next morning, without ether, simply because the patient was not strong enough to finish it unaided. There were throughout no uræmic symptoms. The child was alive and well, and both mother and child have continued doing perfectly well since. The gratifying feature of the case is that the mother has now, three months after the birth of the child, recovered her sight almost entirely.

The points of interest in cases like the above, may be considered as first, loss of sight partial or complete, being liable to occur in acute albuminuria, what percentage of cases recover the sight after labor and what percentage fail to recover it. Is the condition of the structures of the eye similar to the condition where uræmic convulsions take place and where also blindness of a temporary character exists? What are the chances of hæmorrhage into the macula undergoing absorption and what is the condition of the tissues of the retina in acute albuminuria; finally is blindness, partial or complete, liable to arise during pregnancy from causes other than albuminuria; and is a slight form of albumenuria which does not produce constitutional symptoms liable to produce loss of vision.

While a single case may not be of any great value in deciding what our duty is in a similar one, it at least shows that all do not become blind, or fail to recover their sight, and it leaves some hope that a difficult operation, dangerous to the child if not to the mother, need not be assumed to be absolutely necessary where albumen and a few casts exist without other indications of disease.

Instead of quoting the opinions of oculists on this subject, I trust the views held by the profession on the above points will be given by one of themselves.

THE "DUNBAR" CASE.[1]

BY F. K. PADDOCK, M.D., OF PITTSFIELD, *Medical Examiner.*

AT 10.45 P. M., July 4th, 1885, I received notice that George S. Dunbar was found lying in Water street, Pittsfield, dead, with a wound in the back of his head. I immediately repaired to the place, and viewed the body at 11 o'clock P. M.

That part of Water street where the body was found is fifty feet in width, bounded on the south side by the Housatonic River, and on the north by a picket fence, back of which is a vacant lot. The street has no sidewalks. The travelled roadway is fifteen feet in width. On the north side of the roadway there is a space ten feet in width, extending to the fence, covered with grass. South of the roadway, the grass extends down the river bank twenty-five feet to the water. The street is unlighted at night, and the only building on that part of the street is the gas house.

The body lay parallel with the street, upon the grass between the roadway and the fence, with the head toward the east. When first discovered, the body was lying face downward; but it had been rolled over by the person who discovered it, and I found it lying upon the back, face upward. The night was very dark, and the view was made by the aid of lanterns. The body was warm; the face, back of the head, the adjacent hair, and the back of the neck, were discolored with fresh blood. The lids of the left eye were discolored and greatly swollen, presenting the characteristic appearance of a bad black eye, such as ordinarily results from a stunning blow upon the tissues covering the orbit.

At the back of the head, in the occipital region, just

[1] Read at the meeting of the Massachusetts Medico-Legal Society, February 3, 1886.

to the right of the median line, was a wound of sufficient size to admit of the little finger being passed through the skull into the brain, from which warm blood slowly oozed.

Lying beside the body, evidently on the spot occupied by the head before the body was turned over, was his hat, the brim of which was covered with blood, and there was a blood stained spot of grass under and beside the hat, where the blood had evidently trickled from the wound in the back of the head.

The body was dressed in a black cassimere suit. The coat was a loose sack, buttoned at the upper button. The examination of the pockets revealed the absence of his pocket-books and money. The pockets of the coat contained only a white cambric handkerchief and three pistol cartridges, No. 32 calibre. His vest pockets contained a watch key and a cheap Waterbury watch, which was running. In his trousers pockets were a bunch of keys, and two or three blank gas-bills.

Upon the ground, close to the right ankle, as the body lay upon the back, was found a 32-calibre revolver, with five chambers; three of the chambers were empty, one contained a loaded cartridge, and the remaining one, an empty shell. To the handle of the revolver was tied one end of a piece of strong brown twine. This twine measured just ninety feet in length, and lay on the grass along the side of the roadway, the free end being about fifty feet from the body.

It was fastened to the handle of the revolver in such a way as to form a loop, which could be made to hold the hammer in a position half-way between half and full cock. When so placed, the weapon could be discharged by pulling on the string; this would free the hammer and allow it to fall. Experiments made with the revolver afterward showed that the cap of the cartridge would not explode every time the hammer dropped, but would average once in five or six times.

The chief witness at the view was a young man, who discovered the body as he was walking along the street, shortly after ten o'clock, on his way home. He first supposed the body to be that of a drunken man, and he called to two companions he had left upon the river bridge only a moment or two previously, to come to see who it was. One of them lighted a match and identified Dunbar. They then went to the gas house, procured a lantern, and, accompanied by two employés at the gas-works, returned to the body, which they rolled over on to the back, and discovered that life was extinct.

A wagon was procured, and I had the body conveyed to his residence on Howard street. Before leaving the house for the night, I had a search made for Dunbar's wallets, in which he was known to usually carry considerable money, thinking that he might have left them at home when he went out that evening, but they could not be found.

The autopsy was made 10.15 A. M., July 5th, twelve hours after death, in the presence of Drs. J. F. A. Adams, Henry Colt, Jr., William L. Paddock, H. W. Dewey, and S. C. Burton. The body was well nourished and muscular, but without much adipose. Rigor mortis was well marked. The signs of injury were confined to the head only. The face was badly disfigured by the ecchymosed and swollen condition of the lids of the left eye. There was no other appearance of injury to the face. The blood was carefully sponged from the hair and scalp about the wound in the back of the head. The hair was not singed, nor could there be found any powder mark on the scalp. The wound through the scalp was round in shape, and a little larger than the opening through the skull. The edges of the scalp wound, as well as the bone forming the circumference of the opening through the skull, were blackened by lead which had been rubbed off from the bullet in passing through.

The calvaria was removed. The dura mater was found unusually adherent to the skull. In the posterior portion of the falx cerebri was a deposit of bone, shaped like a button, three-fourths of an inch in diameter, and one-eighth of an inch thick. The wound in the skull was irregularly round and situated in the occipital bone, one-third of an inch to the right of the median line, very near the occipital protuberance, just below the semi-circular ridge. The appearance of the wound indicated that the line of flight of the bullet was at right angles with that portion of the bone wounded. Several small spicula of bone were found in the lacerated cerebellum. The wound passed below the right lateral sinus, and extended upward and forward, through the posterior lobe of the right hemisphere of the cerebellum, through the posterior and middle lobes of the right hemisphere of the cerebrum, where, at the upper surface of the middle lobe, the wound changed its direction and passed downwards, forwards, and slightly inwards, and terminated in the anterior lobe of the cerebrum, close to the longitudinal fissure, where the bullet was found, in a position halfway between the anterior and posterior borders of the right anterior lobe, just above the right lateral ventricle. The brain substance was very much lacerated along the course of the wound. The left hemisphere of the brain was uninjured, and apparently in a perfectly normal condition.

The internal surface of the skull was searched with great care to discover any fracture that might have resulted from the concussion of the bullet, or from other sources, but none could be found.

The bone was removed from the roof of the left orbital cavity, as well as the cribriform plate of the ethmoid in order to discover if there was any connection between the bullet-wound and the contusion or injury to the left eye. The orbital cavity was found full of clotted blood, which had infiltrated the cellular tissue behind and around the ball, pressing it forward as far as the optic nerve permitted. The cellular tissue of both lids was also fully infiltrated. There was clotted blood in the left nares, but the bone was found uninjured, and there was not any fracture extending from the wound in the occipital bone made by the bullet.

The bullet was very much flattened and its circumference was irregular and jagged, and presented the appearance of having struck the bone squarely on end; the base of the bullet was not bruised and exhibited the creasing marks of the barrel of the revolver and exactly fitted the empty shell found in the chamber of the weapon. The three cartridges found in the coat pocket exactly resembled those in the revolver.

The developments attending the view and the autopsy rendered the case problematical. Was it suicide or was it murder? Did this man shoot himself or was he shot by another? In order to intelligently consider these questions and properly weigh the evidence favoring the two theories, it is necessary that

we should know something of the history of the deceased.

George S. Dunbar was born in 1836, in Pittsfield, where he lived until his death. His father kept a grocery store and a fish market. He was educated at the Grammar School. At the age of sixteen he was apprenticed to a mechanic and learned the machinist's trade. After attaining his majority and finishing his apprenticeship, he was employed in a woolen factory as machinist. He was married at twenty-eight years of age, and his wife kept the factory boarding-house, while he worked at his trade in the mill. At the age of thirty-three, he was appointed superintendent of the works of the Pittsfield Gas Company, a position he had ably filled for sixteen years at the time of his death. Soon after receiving the appointment of superintendent, he bought a house on Howard street, near the gas works, where he has since lived. Physically he was strong, vigorous, and very active. Although rather spare in form, he was muscular and possessed great endurance. He never had any severe illness, with one exception, and that was a temporary attack. On several occasions he had been overcome by the inhalation of illuminating gas, while at work in an excavation endeavoring to find a leak in the gas-pipe. About four years ago, he was carried home in a paralyzed condition from this cause, and for twelve hours afterward, he was delirious and had several severe convulsions, during which opisthotonos was well marked. He recovered in forty-eight hours and was at work again.

His duties as superintendent were arduous. Leaks in the gas-pipes, in various parts of the town, as well as the locating and laying of new pipes he attended to. The monthly and quarterly record of the numerous meters, he took himself, besides making out and collecting a great many of the bills.

He was in the habit of carrying with him in a large wallet a considerable amount of money, varying from fifty to two hundred dollars, which he took no pains to conceal, and exposed it freely whenever he happened to be about town when making change, as he collected the gas bills. He was called upon by everybody in town using gas, to correct any fault found with the illuminating vapor. The prompt fulfilment of all these duties demanded constant activity early and late, and Mr. Dunbar was always equal to the emergency. He was strictly temperate and scrupulously honest in all transactions. However trying or vexatious were the demands and whims of unreasonable gas-takers, he always appeared cheerful and unruffled, and faithfully endeavored to relieve the cause of dissatisfaction. He had a pleasant home and a happy family, consisting of a wife and four children. His salary as superintendent was more than sufficient to support them comfortably, and he was able to save a small amount of his annual income. Some eight years ago, he and his brother bought some stock in Wall street, not not as a speculation at first, but as an investment. In the course of a few years, however, they became somewhat familiar with the stock-market and were more or less infatuated with the excitement and the possibilities of dealing in stocks, and they began to speculate, at first carefully and successfully, so much so that when the brother died of cerebro-spinal meningitis in 1881, they were reported to have made between twenty and forty thousand dollars. It is a singular if not a significant fact, that George's death occurred on the fourth anniversary of his brother's death. It is not known that George met with any serious losses, subsequently, until the spring of 1884, when, by an unfortunate and unexpected change in the price of stock which he had bought on a margin, he lost all that he had made; and it is supposed that he also lost a small amount that he had borrowed. For the fifteen months following this reverse there is no evidence that he dealt in stocks at all, and in April, 1885, he settled with his broker in New York and withdrew the balance of his account. He did not allow his interest in stocks to interfere with his duties as superintendent of the gas company. The business was carried on by telegrams through brokers in New York. He developed a considerable degree of ingenuity in the line of his business as superintendent. He made several practical inventions, one of which is very successfully used for lighting and another for extinguishing the street lights at night. Within the last five years he has paid considerable attention to life-insurance as an investment. As soon as it was discovered by insurance agents that he was interested in the subject, he was beset by representatives of various companies. At first he stated that he wanted insurance to the amount $25,000. He got $21,000 in regular life-insurance companies, but finally several declined to insure on account of his having had convulsions after inhaling the illuminating gas. This seemed to annoy him and induce him to seek insurance in companies and mutual benefit associations that were not so particular about their risks, and he ultimately secured $66,000 of insurance, divided among various companies, associations and fraternal societies.

Several times he noticed that he was followed by one or more ill-looking men, as he made his rounds of observation of the burning of the gas at night, as he walked through the back streets, and he mentioned the fact to the officers of the gas company. They cautioned him about exposing his money so freely when he had occasion to make change on the street, and advised him to carry a pistol. He replied that he was not afraid, that he never carried a pistol, and he disliked to do so. At the inquest there was no evidence to show that he ever carried one, except the testimony of a hardware merchant, who stated that he had sold him a revolver last April, similar in pattern to the one found by his body; but on subsequent examination by the judge, he and his clerk made such conflicting statements that the court was led to believe that the merchant did not sell him the revolver found by the body, although he may have sold him a different one. His family knew that he owned two revolvers, and they were both found in his house in their usual places after his death.

I speak quite confidently of Mr. Dunbar's character and habits, because I had known him rather intimately for fifteen years. Our offices were on the same floor of the same building and adjoining, so that, in addition to my knowledge of him as his family physician, I saw him nearly every day as he was about his business. At the time of his death he had an annual income of between three and four thousand dollars, which was more than enough to comfortably support himself and family. His assets, as near as could be ascertained at the inquest, were $18,170, while his indebtedness was $22,200, making a difference of about $4,000, which he owed for borrowed money. This amount with his good health and regular income could

hardly have caused him especial anxiety, or have been the cause of despondency.

The day preceding the evening of his death was spent apparently as usual, and he went to his home about six o'clock, P.M., and reclined upon the sofa during the evening, the time being occupied in reading and in conversing with his family. Between half past nine and ten o'clock he left the house, saying that he was going to investigate a reported leak in the gas-pipe under the Elm street bridge, near where his body was found shortly after ten o'clock. In fact, he was seen by several people walking in a direction which he would naturally take in the night to go to this bridge; but whether he had been there and was returning by the gas-house when he met his death, or was on his way to the bridge when it occurred, is unknown.

The inquest was held by Judge Tucker, beginning a few days after the death of Dunbar, and continued for several weeks. Every person was examined, who, it was supposed, could throw any light upon the cause of death, whether theoretical or practical.

Among the medical examiners called to testify, was Dr. D. B. N. Fish, of Amherst, whose investigations regarding powder-marks upon the skin, in the event of bullet-wounds from pistols held near the body, rendered his experience and experiments of value, in determining the question of possibility of a person shooting himself as Dunbar was shot, with the revolver found by the body, without exhibiting powder marks on the hair and scalp about the wound. The inquest was conducted with care and perseverance, but nothing in the testimony positively indicated the precise method of the shooting. Several detectives were employed, who very soon came to the conclusion that it was a case of suicide. One of them discovered a mark or crease across the sole of the right shoe which Dunbar had on when found, that might have been made by the twine that was attached to the handle of the revolver, indicating that the twine had been drawn tightly across the sole of the shoe with the left hand, while the right hand held the weapon in position for firing. Dr. Fish testified that, without using the twine, the revolver could possibly be fixed, and fired twenty-six inches from the head so as to make a wound like the wound in Dunbar's head, without producing any powder burn or mark upon hair of scalp.

Three days after Dunbar's death, his wallet and pocket-book were found just across the unoccupied field, on an ash-heap, back of a store-house, about thirty-six rods from where the body was found. They contained no money; one of them was open and the other closed, with its strap tucked into the loop.

The testimony of the medical witnesses differed in regard to the cause of the extensive ecchymosis of the lids of the left eye and the effusion of blood about the ball. All but two thought it could only be accounted for by a severe blow upon the eye. Two, however, considered it possible to have resulted from the blow or shock of the bullet upon the back of the head, although there was no fracture of the base of the skull or any injury whatever to the bones entering into the formation of the orbital cavity.

The judge's report of the inquest was very elaborate and complete, consisting of over twenty-six pages of legal cap. In conclusion, he says: "It seems clear that the death was either a murder, with an attempt to make it appear to be a suicide; or a suicide, with an attempt to make it appear to be a murder. A careful consideration of all the facts compels me to the conclusion that Mr. Dunbar committed suicide. This theory explains all the facts but one; this exception is the injury to the left eye. The evidence leaves it doubtful whether this injury was inflicted by a blow or was the result of the shock of the bullet-wound. If the later theory is true, then it is not inconsistent with suicide: if the former, then suicide seems impossible.

"I find and certify that George S. Dunbar of Pittsfield, Massachusetts, shortly after ten o'clock on the evening of July 4th, 1885, on Water street in said Pittsfield, came to his death by a bullet fired from a pistol, which bullet entered the back of his head, and that said pistol was discharged by his own hand.

(Signed), JOSEPH TUCKER.
Justice of the Central District Court."

The absence, at the inquest, of more positive evidence of murder, renders, of course, the finding of suicide justifiable. Yet there are circumstances connected with the case that seem to point quite positively to the conclusion that he did not shoot himself:—

(1) The black eye is incompatible with the theory of suicide.

(2) The situation and direction of the wound indicate that the revolver must have been held in a position almost, if not quite, impossible for the hand of the person shot, without causing powder marks or burns upon the hair or scalp.

(3) The fact that the pocket-books were found empty in a locality where they would naturally have been examined and left by a thief who had committed a murder and escaped through the field adjoining, a place where sufficient light could be obtained to examine the booty without being seen. If Dunbar had himself left them where they were found, he would, to escape observation, have travelled a long circuitous route from the place where he was last seen.

Besides these, there are other circumstances that might be mentioned, which militate against the probability of suicide. If he committed suicide he evidently meant to have it appear to be a murder. Upon no other theory can the long string, the fact that he was shot in the back of the head, the placing of the pocket-books, and the locality selected for the deed, be accounted for. If such was his intention, then an alert, intelligent and ingenious man, in the full possession of his faculties, laboring under no especial excitement, carefully prepared and carried out his scheme in the most bungling and foolish manner. Why should he have attached a useless string, ninety feet long, to the revolver and left three cartridges in his pocket? On the other hand, if he was murdered, these evidences of suicide are just what would have occurred to his assassin, to throw off the suspicion of murder. Which of the two theories is the true one, time may fully reveal.

If he committed suicide it is improbable that any further evidence of the fact will ever be added to what is now known. If he was murdered, there is yet hope of the discovery of the assassin.

— The American Neurological Society will hold its annual meeting at Long Branch on July 21. The Otological at New London, on July 20. The Ophthalmological at New London, on the 21st.

CASES OF TRACHEOTOMY IN DIPHTHERITIC CROUP.

BY AUG. M. TUPPER, M.D., OF ROCKPORT, MASS.

Trousseau is credited with saying that "tracheotomy badly performed, but well treated afterwards, will end favorably in a third of the cases, whereas tracheotomy excellently executed but badly treated afterwards will almost invariably be followed by a fatal termination."

Meigs and Pepper say, "whenever it is in any way possible, the constant presence, day and night, of a physician or student of medicine should be secured for four or five days after the operation . . . the child should never be without the presence of some one competent and ready to render the prompt assistance which is frequently necessary to avert instant death."

J. Lewis Smith, in his "Diseases of Children," remarks that "no surgical operation more imperatively demands intelligent and attentive after-nursing than tracheotomy." Now, while I entirely agree with the above quotations, and can well understand the relief and comfort it must be to the physician to know that during his absence his patient is in the hands of a medical friend or skilled nurse, I believe that many times we can attain success under most unfavorable conditions, and when we have to depend entirely upon ourselves for the care, as well as the treatment, with what can be taught the parents and friends at the time. By making frequent visits, and spending the nights, if possible, in the same house with the patient, we shall often be able to succeed, without the trained assistance which is so desirable when it is possible to procure it.

The following cases, by the recovery of two out of the five, go towards proving this, I think, particularly the last one, and it is in the hope that they may prove interesting and encouraging, especially to those who, like myself, are living away from the medical centres, and where the professional nurse is not at hand, that I venture to report them. All were diphtheritic, as proved by the presence of false membrane in the fauces, and the prevalence of diphtheria in the vicinity, and are reported from notes written at the time, and partly from memory.

Case I. A boy, seven and a half years old, who recovered, has already been reported in the Journal, October 11th, 1877.

Case II. Female, aged six years and nine months. Went to bed September 21st, 1879, apparently well. The next morning (September 22d) did not want to get up, and complained of headache and sore throat. When I first saw her, the tonsils were very much swollen, and large patches of diphtheritic membrane could be seen upon them. There was a copious discharge from the nostrils, and the breathing was labored.

September 23d. This morning she is much worse, the swelling in the throat has increased, the tonsils nearly meeting, and her breathing is much obstructed. The nasal discharge has also increased. In short, she presented the appearance of one of those severe cases of diphtheria with which we are all familiar, with the addition of the croupy symptoms.

3 P. M. Growing worse rapidly, and the respiration being still more embarrassed, I decided that tracheotomy offered the only chance, and that a very slight one, on account of the great amount of systemic infection. However, the operation was done at 4 P. M. The trachea was small and deeply situated. At first we thought the tube was too large, and tried wire bent in the shape of hooks, but could not make it answer very well, and finally got our only canula in place. She was much relieved, and at 10.30 P. M. was sleeping pretty comfortably, but her pulse was very small and too rapid to be counted. The nose continued to discharge freely. We gave her injections of brandy, milk, and eggs as frequently as the rectum appeared likely to retain them. Did not try to make her swallow, the throat being so much swollen as to make it very difficult for her to take nourishment by the mouth. The operation was of great relief to this patient, and she continued comfortable until 2 A. M. of the 24th, when she died very quietly and easily.

I have sometimes felt that this child had better not have been operated upon, but when we read what such a man as Jacobi says about these cases,[1] namely: "no alleged contraindication to tracheotomy, whether the tender age of the patient, or a complication with either an inflammatory or an infectious disease, must be considered valid. The one strict indication for the performance of tracheotomy is when the diagnosis of pseudo-membranous laryngitis is undoubted. The increasing dyspnœa, cyanosis, and approaching asphyxia, with the certainty that a well-directed and efficient medicinal treatment has been, and in all probability, will be useless; even under these circumstances, there is no mathematical certainty. The matured experience of a well-informed and thoughtful physician will commit but few errors. If there be the slightest doubt, the operation ought to be preferred to suffocation." When we read such conclusions, we must feel that we have done for the best, given our patient every possible chance, and, at least, a merciful death.

Case III. Boy, aged six years and two months. Taken with diphtheria November 26th, 1879. Was hoarse from the first, but had no difficulty in breathing until Wednesday, December 3d, when he began to breathe harshly, and to cough occasionally.

Thursday, 4th. The difficulty in respiration had increased, and he had several attacks of spasm of the glottis.

Friday, 5th. He seemed better in the morning, and continued so until 4 P. M., when he grew worse, and began to suffer from dyspnœa continuously. The difficulty in breathing increased very much until 10 P. M., when tracheotomy was performed. There were several large veins in the line of incision, and the hæmorrhage was considerable, and when the trachea was opened, blood escaped into the windpipe and nearly suffocated him, but by vigorous effort, and performing artificial respiration through a catheter, he was resuscitated. He soon fell asleep, and passed a very comfortable night.

December 6th, 2.30 P. M. Has coughed a good deal to-day, but not raised much, still he seems in pretty fair condition. His pulse has been below 100 up to last night, when it reached 130 to 140; since he recovered from the operation it has been about 120. Respiration not counted, but certainly as high as 60; it is now 48, and he is sleeping quietly. I have not been able to keep the inner canula in place; he coughs very much, and does not breathe as well as when he has the outer tube only. Not much false membrane has been seen, and before the operation it had de-

[1] Pepper's "System of Medicine," Vol. III.

creased; only a patch half as large as the thumb-nail remained on the back of the right side of the throat.

December 7th, 9 A. M. Was pretty sick yesterday afternoon and last night; breathing a good deal obstructed, partly from mucus and partly from false membrane, at least I think so, from the sound of the cough and character of the breathing. There is a peculiar clicking sound at the end of inspiration, as if a piece of membrane partly detached was acting as a valve. I have heard this sound since, and regard it as an ominous sign, as significant of an extension of the disease below the opening. I am obliged to use the outer canula only most of the time, as he does not breathe as well with the inner tube in place. Took the tube out completely last night, at seven o'clock, and again this morning, at half-past six; neither time did it relieve him much, showing the obstruction to be in the trachea, and not in the canula. Pulse and respiration remain about the same, 120 to 130, and 45 to 50, respectively. Just now I removed the tube again, and think he seems easier for it. Intend leaving it out for a while, as there seems to be phlegm and membrane not completely detached, and I fear it may be too large to get out through the canula.

December 8th. The distress in breathing continued to grow worse, the pulse rising in frequency and exhaustion coming on. He finally died of asphyxia at nine last night, after suffering very much for six hours previous.

He never coughed up any false membrane and very little mucous, although at times it seemed very loose. This case was at first a very promising one, more like a case of ordinary croup, as very little membrane was seen upon the fauces and the constitutional symptoms were very slight. I could not even get him put to bed until he began to have distress in his breathing. His hoarseness made me feel uneasy of course, and I watched him very closely all the while. It illustrates how difficult it is to tell how far the diphtheritic membrane may go before it has reached its limit, and also how late in the case we may have the larynx and trachea attacked, even after the membrane has begun to disappear from the throat.

CASE IV. Boy aged nine years and two months. Taken with diphtheria December 31st, 1880. First seen January 1st, 1881. Has had a cold for two or three days. Tonsils swollen and patched with false membrane.

January 2d. Mother says he had a croupy attack last night and that his cough is croupy.

January 3d. Croupy symptoms have increased and his breathing has become so much obstructed that tracheotomy was performed at ten this morning. The operation was a very easy one, he was much relieved, and now, 10 P.M., the breathing is very easy and noiseless and he is sleeping like an infant.

January 4th. Rested well last night, but coughed a good deal, and I have had to take the inner tube out, consequently have a good deal of trouble in keeping the canula clear. At noon he had a severe attack of dyspnœa and his mother cut the tapes and removed the tube, the removal being followed by violent cough and expulsion of a large piece of false membrane, a cast of the trachea, an inch long. On my arrival, some two hours after, I reintroduced the tube, and although at first he breathed hard and coughed a good deal, he is now, 3.30, P.M., quite easy.

January 5th. Had a very comfortable night last night, but this morning the tube had to be left out.

P.M. Breathing becoming more and more obstructed, the disease has evidently gone below the opening. He suffers a good deal and requires constant use of the atomizer. Has frequent paroxysms of dyspnœa, and died in one at 6 P.M. The pulse did not go over 130, and he took his food and medicine well up to the last moment.

I might mention that so afraid was every one of the disease about that time that I had a difficulty in getting anybody to come in and assist Dr. Manning and myself during the operation, and the young man I finally procured was not allowed to enter his sister's house, where he boarded, for several days, for fear he should bring the disease to some of the family.

CASE V. Female, aged two years and eight months. First called November 22d, 1885. Her mother says she has had a cold for two or three days and been hoarse. I found her breathing harshly, with a croupy cough and all the symptoms of commencing laryngeal obstruction. Did not look in her throat, it being after lamplight I knew I could not see satisfactorily. Commenced the bichloride treatment, ordered steam to be generated in the room, and gave an emetic.

November 23d. Visited her early and found the symptom of obstruction very much increased. Examination of the fauces showed both tonsils coated with false membrane. Advised tracheotomy and performed it as soon as I could get help and instruments. Before the completion of the operation, on account of the failure of the pulse, although the respiration continued good, the trachea had to be opened before it was fairly exposed. Brandy was administered hypodermically and she soon rallied.

This case did as well as one could wish, there never was any trouble from obstruction and the breathing was easy and most of the time noiseless, with the exception of one night, but by using the atomizer faithfully and exciting cough by passing a feather down the tube, relief was obtained and there was no further difficulty on that account. All attempts at removing the tube permanently failed up to December 27th, almost five weeks, when she was able to breathe through the larynx comfortably for a short time. Until then she could do very well about long enough to remove and clean the canula and sew on new tapes, when she would begin to be distressed and the tube would have to be replaced, and quickly, too, sometimes. After December 27th, we would remove the inner tube and cork up the outer, which had a slot in it, for several hours each day. Still the canula could not be removed permanently. She could breathe through the larynx with the tube in place and corked, but if it were taken out she would have what seemed to us spasm of the glottis. She coughed a good deal, and often the expectoration would be bloody, occasionally pure blood. The bloody expectoration continued until I changed the tube for a smaller one.

On January 5th, 1886, I took out the canula, and staying some little time found she was breathing well, and as each time it was removed the mother was instructed how to replace it and made to do it herself, so she could respond to an emergency, I left, directing her to reintroduce it at 4 P.M., and before that if she began to be distressed. At the appointed time the mother attempted to replace the tube, and failing sent for me. On my arrival, two hours later, I found the

granulations which existed around the outer edge of the wound had closed in and filled up the opening. I tried to get the canula in and failed likewise, but finding the child breathing well, without any distress, did not persevere in my attempts, but decided to leave matters as they were. Suffice it to say the child slept well all night and never had any trouble afterwards, and in about two weeks the opening was entirely closed.

It is this case I would speak particularly of, for there are several unusual and interesting features about it, one of which is the size of the tube. It is advisable to use as large a tube as can be introduced easily into the trachea. For the first few weeks I used one which was slightly larger than that used in my first case. It was inserted very easily, but I think was rather large and probably accounted for the bloody expectoration. It was afterwards changed for the same one worn in Case I, and it will be remembered that he was seven and a half years old, while this patient was only two years and eight months. Dr. R. W. Parker, in the *Lancet*, February 7th, 1885, says: "slight differences in the length of the tube, in depth from the front opening to the angles and in calibre, I believe, often turns the balance one way or the other. A tracheotomy tube, like a boot, must fit comfortably, or it cannot be worn without injury." Yet here are two children, with almost five years differences in their ages, wearing the very same tube and both recovering.

Another feature is the rapid filling up by the granulations of the external orifice of the wound, thereby preventing the reintroduction of the tube when left out a few hours, which might have proved a very serious matter and illustrates the importance of keeping these granulations down by the use of caustics or scissors. The most interesting and unusual complication is the prolonged retention of the canula, forty-four days. In any case it is advisable to remove the tube at the earliest moment which is practicable, as the prolonged retention may be a source of danger in several forms, such as ulceration, hæmorrhage, and a formation of granulations in the trachea.

Meigs and Pepper, after quoting Trousseau as saying the removal may be delayed fifteen to twenty-four or forty-four days or even longer, give the causes as summed up by Mr. Mash, as:

"1st. Obstruction of the larynx by false membranes which have been known to linger in its cavity for at least fourteen days after this operation.

"2d. A chronic inflammation and thickening of the mucous membranes of the larynx which may remain after the acute disease has passed off.

"3d. A narrowing or complete obliteration of the passage of the larynx by a growth of granulations above and around the canula.

"4th. An impairment or complete loss of those functions of the muscles of the larynx which regulate the admission of air through the rima glottidis.

"5th. Adhesion of the opposed surfaces of the vocal cords."

Another cause which may delay the removal is nervousness. The child accustomed to breathe through the tube, on finding it removed and air passing through the natural channel, becomes alarmed and spasm of the glottis ensues, and this of course increases the terror, each reacting upon the other. Parker relates a case in which the removal was delayed in part on that account. To which of these causes the difficulty was due in the present case, it is hard to determine positively, but I am inclined to attribute it to two, namely, the presence of granulations in the trachea and also to spasm, the latter being induced part of the time by the existence of the granulations. The fact of there being granulations at the external orifice would go to prove the probability of their presence also at the inner. The pressure of the tube keeps them back, but a short time after its removal they swell up and if they are sufficient in quantity may occlude the trachea, at least that is the explanation Parker gives. The bloody expectoration while wearing the larger tubes was also indicative of irritation and ulceration perhaps. It is rather provoking to read in the text-books of the causes of the delay in the removal of the canula, but to find nothing on the treatment of such complications. Parker recommends the local application of nitrate of silver fused on a silver probe, suitably bent, and applied to those parts on which the granulations are supposed to exist, or a solution of the nitrate, thirty grains to the ounce, a few drops allowed to trickle into the trachea, one of which methods I should certainly adopt in another case. His articles in the *Lancet*, January 24th, 31st, and February 7th, 1885, are valuable ones and well worth reading. Thus far I have said nothing about the treatment of these cases, but medicinally it consisted of a continuation of a Tr. Chloride of Iron and Chlorate of Potash mixture given frequently, and small doses of a solution of carbolic acid also administered frequently, when they took anything, for in some of them it was impossible to give any medicine except a little carbonate of ammonia; of course they were fed as nutritiously as possible. Trousseau states that as soon as the trachea is opened the diphtheritic process comes to a standstill in the pharynx. The great point is to keep the canula clear, and in order to accomplish this the inner tube must be frequently removed and cleaned. My plan has been whenever the breathing became noisy or obstructed, to use the steam atomizer, placing the mouthpiece close to the opening, protecting the patient from being wet by the spray by means of towels, etc., when, if not improved by the inhalation, remove the inner tube and clean it, and if neither of these measures succeed in rendering the respiration easy, steam through the outer canula and pass a feather down into the trachea so as to excite cough and expel the phlegm or membrane which is very likely the cause of the difficulty. The steam atomizer is invaluable in these cases, in my opinion, but I think that steam from water alone or a weak solution of carbolic acid is as useful as any of the so-called solvents. I have seen the little patients motion and point for the atomizer, because it relieved them, and one poor little fellow in his agony would grasp the mouthpiece and hold it to the opening himself, thereby giving mute but eloquent testimony of its utility.

It has been noticed that in some of these cases we were obliged to leave out the inner tube, because the breathing was easier with the single outer canula only. Why this was I do not know, unless the instrument was too small. Profiting by experience, I should hereafter use larger tubes at the same age. Possibly the result might have been more favorable had I been better provided. The rooms were kept warm (75° to 80°), and the atmosphere charged with steam, but in the last case the amount was small, owing to circumstances.

To strengthen my assertion that tracheotomy can be successful in diphtheria under most unfavorable conditions, I would like to relate some of the circumstances of the last case. The father was a teamster and the home none too comfortable, while the hygienic arrangements left much to be desired. As soon as the disease was declared diphtheria all the neighbors at once departed, leaving the mother and the doctor to do all the nursing and take care of the family besides, for the father having had a brother return from the West after a long absence, celebrated his return and the "miracle" which was being done on his child, in the too common manner, with the usual result, and was of no help for the first two or three days. The first night about 2 o'clock I came down stairs to see how matters were progressing, to find the mother and the patient sound asleep on the bed, and this brother referred to, who had promised to keep awake and watch, lying on the floor also asleep. The mother on the fourth day was attacked by the disease, but the attack proving light, was able to keep on her feet and attend to the child.

In regard to the operation itself, it is not generally a difficult one, but it is very encouraging to those of us who are not in the way of seeing or doing much surgery to find an author like Trousseau saying "provided the canula be introduced into the trachea it really matters little how that has been accomplished, whether the operation has been performed with more or less dexterity, or with more or less rapidity, the result is the same provided there has not been hæmorrhage," and again, Parker, who writes "It is hardly probable that the various structures found in front of the trachea will be individually recognized during the performance of a tracheotomy."

If one will look through the medical journals for the last ten years he will see how much more frequently the operation is done than in the past, and how many more successful results been obtained. I well remember how an old, experienced and able physician discouraged the attempt in my first case, because it was diphtheritic, but I venture to predict that the time is coming, if not here already, when the physician will be just as much expected to open the trachea of a child dying from croup, diphtheritic or not, as he is expected to set a fractured limb or tie a wounded artery.

Since writing the foregoing paper, I have been called to a neighboring village in consultation, to see a child with croup, on whom I operated. The nursing was done entirely by the relatives, the case doing perfectly well and the canula removed permanently on the twelfth day. The operation was done in the kitchen, the patient remaining there until well, it being the only room where it was possible to get the necessary amount of steam generated.

THE DELAYED REMOVAL OF TRACHEOTOMY TUBES, WITH CASES.

BY ROBERT W. LOVETT, M.D.
Formerly House Surgeon at the Boston City Hospital.

AFTER the performance of tracheotomy in children there is seldom any difficulty in dispensing with the use of the trachea tube after a few days. At the Boston City Hospital in about three hundred tracheotomies there have only been four cases which presented this difficulty. Ordinarily at the Hospital the tube is removed on the fifth, sixth, or seventh day by cutting the tape and quietly taking it out. No preliminary testing of the passage of air through the larynx by stopping the tube is attempted, and in the overwhelming majority of cases laryngeal breathing is fully established by the time that the tracheal opening is cicatrized. The following four cases are the only ones in which tubes were worn for any considerable time.

I. J. E. C., a fat little boy fifteen months old, a nursing baby, was admitted with his mother May 29, 1885. He had been distressed for breath for two days and at the time of admission he was suffering from very severe dyspnœa with retraction of the soft parts of the chest at each inspiration. There was grayish membrane upon both tonsils, and the glands of the neck were much enlarged. Tracheotomy was at once done by the House Surgeon, and afforded relief. His progress was very favorable, he nursed quite well, drank a few ounces of milk daily, and was but little prostrated. On the sixth day (June 4) the tube was taken out at 11 A.M. and the child breathed quietly without it. At 3 P.M., of the same day, he had such a violent attack of dyspnœa that he would have died had not the nurse at once replaced his tube. He rallied quickly from the extreme prostration caused by this attack and breathed without further trouble until three days later (June 7) when the tube was removed again, but dyspnœa came on at once and it had to be replaced. For two weeks from this time his condition continued the same. His tube was taken out daily, but he was unable to breathe without it and it was always necessary to put it back at once. The wound had closed around the tube and no exuberant granulations were to be seen. It seemed as if the trachea collapsed when the tube was taken out, and so shut off the entrance of air to the lungs. Air certainly passed through the larynx when the tube was stopped, and he began to talk aloud June 22d, in a husky but fairly loud voice. The wound was painted daily with a saturated solution of alum and a smaller but still fenestrated tube was put in. He went out of doors daily and improved in his general condition until July 20, when he was discharged wearing his tube. He reported at the Out-Patient Department from time to time to Dr. Hooper and was under his care until November 15, 1885, when he was readmitted to the hospital for another attempt to remove the tube. It came out with difficulty and a small mass of granulation tissue which had grown through the fenestrum into the tube, was pulled away with it. The boy struggled and strangled a little, but in five minutes he was breathing quietly and the tube was left out, although it had been intended to insert a smaller and a non-fenestrated tube. He had a very croupy cough for two nights and breathed rather noisily when asleep, but without distress. November 21, 1886, he left the Hospital; the wound was closed, his voice clear and natural, and his breathing perfectly normal. He has continued in this condition.

II. Albert W., four years old, was admitted July 5, 1885, suffering from severe dyspnœa. He had had whooping-cough three months previously, and was now suffering from measles, the eruption of which was just disappearing. He had been distressed for breath for three days, and at the time of admission he was struggling with every inspiration and somewhat cya-

notic. Tracheotomy was at once done without ether by Dr. Bolles and complete relief was afforded. He received the usual treatment, one-sixtieth of a grain of corrosive sublimate every hour, and milk and brandy. He got along very well and on the fifth day (July 10), the tube was taken out. Two days afterward he had a violent attack of dyspnœa and the tube was replaced. For a week after this the tube was taken out for a little while each day and the wound painted with copper sulphate and glycerine, on the supposition that exuberant granulations were the cause of the trouble. July 22, the boy was able to get along without the tube and it was taken out and the wound treated with tannic acid solution. July 30, the boy was playing about the ward all day, the wound had wholly closed, his voice was clear and his general condition excellent. That night he had a croupy cough and noisy respiration. This continued through the night and at 6 A.M., July 31, he had an attack of violent dyspnœa with much retraction of the abdomen and soft parts of the chest with each inspiration. The mother refused to have tracheotomy done again, but at 8.30 A.M., he was failing so rapidly that she asked for the operation and tracheotomy was at once done without ether by the House Surgeon. The operation was in the line of the old scar and by no means an easy one. Immediate relief followed the opening of the trachea, the boy rallied quickly under strong stimulation and was soon convalescent.

On the sixth day (August 5), the tube was taken out and left out until the next day when it had to be put back and left in until August 19, when it was left out for thirty-six hours, but an attack of dyspnœa coming on in the night made it necessary to put it back with all possible haste. August 25, a smaller and non-fenestrated tube was substituted for it and September 1, 1885, the boy was discharged wearing that tube. His voice was clear and his condition excellent.

October 3, 1885, he was readmitted, having had his tube plugged for a week, both day and night, and the tube was at once removed. Beyond a croupy cough for a day or two he had no trouble and was discharged October 14. The wound was closed, his voice still clear, and his condition is still good. In neither Case I or Case II was it possible to get a view of the larynx although repeated attempts were made.

III. Mattie S., three years old, was admitted May 1, 1881. Dyspnœa was severe and tracheotomy was done at once without ether, by Dr. Ingalls, and the progress of the case was very favorable. On the seventh day (May 8), the tube was taken out, but an attack of dyspnœa came on in forty minutes and it had to be put back. It was left in for a week and a second trial made May 15; result the same. In another week air was found to pass through the larynx, but the tube could not be dispensed with. June 3, ether was given and the trachea was stitched to the skin around the edges of the wound, but the tube had to be replaced nevertheless. Some improvement followed this, and by the middle of June the tube was kept out most of the time, and only put back temporarily when it was needed, but in a few days her general health failed, and by the 30th she was wearing the tube again. July 5, 1881, she was discharged still wearing it.

From time to time attempts were made to remove it, but all proved unsuccessful. On the evening of July 19, 1883, two years after discharge, the tube had been taken out and cleaned, and her mother was about to replace it, when the little girl said "I do not want it any more, you need not put it in." She has never had any further trouble.

IV. Clara Z., two years old, had tracheotomy performed at the Hospital for diphtheritic laryngitis, June 16, 1883, by Dr. Ingalls. On the following day she had extensive emphysema of the chest, but this soon disappeared and she got along very nicely. On June 26, the tenth day, the tube was taken out, but had to be replaced in an hour as the child was unable to breathe without it. By July 4, she could breathe through the larynx when the tube was stopped but she had a cough and could not breathe when the tube was taken out. She had a variable progress, and by the early part of August she could not get along without it, even for a minute. At this time she was going out daily and was in good condition. August 13 the inner tube would not go in because of granulations sticking through the fenestrum of the outer one, and August 16, 1883, she was sent to the Children's Hospital to be under the care of Dr. Langmaid. A non-fenestrated tube was substituted for the one that she was wearing, and the size of that was gradually diminished by putting in a smaller and a shorter one every few days. In three weeks she was discharged well, with the wound closed.

The cause of the difficulty in this class of cases is not always clear, but certain pathological conditions have been proved to exist in some of the cases. The commonest of these causes seems to be the obstruction of the air passage by exuberant granulation masses growing from the trachea walls. The irritation caused by the sharp edge of the fenestrum in the trachea tube is probably the cause of much of the trouble, and twenty years ago, Trousseau called attention to the fact that the fenestrum was a useless and a mischievous thing. No tube of ordinary size completely fills the trachea, and air enough passes around it to allow the child to breathe through the larynx when the tube is stopped, if such a process is thought necessary before the final removal of the tube. Again, there is a tendency in certain cases to the formation of exuberant granulations inside the trachea upon the cicatrix during or after the closure of the wound. These granulations may be of the ordinary type, in masses, or worse, moved to and fro by the current of air passing up and down the trachea; they may become pedunculated, and form one or more laryngeal polypi of the size of a pea attached to the wall of the trachea by a pedicle of variable length. Both these conditions have been several times proved by autopsy, by laryngoscopic examination during life, and on opening the trachea to relieve the dyspnœa caused by them, they have been seen and removed.[1] These polypi are a mere consolidation of granulation tissue structure, although they resemble it but little in gross appearance.[2] Prolonged wearing of the trachea tube is a frequent, but not a necessary cause of this complication.

The class of cases next most common is where the trouble is caused by a spasm of the glottis, the reason for which is very obscure. It is suggested that the cold air, going through the larynx for some time unused to its passage, excites a reflex spasm. Again, that the muscles have been in disuse so long that, unless the constant attention of the patient is directed to the breathing, dyspnœa ensues. This accounts for

[1] Koch Archiv fur Klin Chir, 1876-77, xx, 544. Meyerson Wiener Med. Presse, 1884, p. 880.
[2] Ross. Edin. Med. Journal, xxviii, 788.

the fact that children have been able to do without their tubes except during sleep. At any rate, for some reason or other, there is a profound disturbance of the innervation of the larynx in which the mental element is very strong. Death has repeatedly occurred in these spasms. Blachez [3] tells of a case where a boy had been without his tube only a very short time, after wearing it for over a month. He pinched his finger in the door, became angry, and died at once of suffocation. There was nothing found at the autopsy to account for his death. Kriushaber,[4] however, lost a case with the same symptoms, who proved to have had a polypus form on the cicatrix. The child had worn a tube for two months, the wound had closed, and his voice was clear. His father and two other physicians were discussing his case in the room and wished to see the scar. His mother started to undress him, he struggled, a paroxysm of dyspnœa came on, and he died before help could be afforded. Children in this class of cases have been repeatedly deceived into going without a tube by all sorts of devices, such as wearing a tube without any lumen, a shield without any tube, and the like, and even in a case related by Millard,[5] a little girl whose trachea wound had closed, wore her tube around her neck hanging by a string, and every effort to take it from her, caused so serious a paroxysm of dyspnœa that her life was endangered, and it was only by the most persistent effort on the part of Millard that she was enabled to get along without it.

True post-diphtheritic paralysis of the cords is a third and still less common cause of the trouble. In most cases where there is obstruction a laryngoscopic examination has shown no paralysis, but Gerhardt [6] recorded a case observed during sleep where there was true paralysis after wearing a tube for three weeks. It is often very hard to distinguish this condition clinically from the nervous spasm mentioned above; the paralysis is of course more regular and not likely to be found more than three months after the occurrence of diphtheria.

Collapse of the trachea walls and cicatrical contraction of the trachea and larynx only remain to be mentioned as possible but infrequent causes of this trouble. The latter is not a condition that we should expect to find immediately after tracheotomy, but Steiner found a larynx completely blocked up by scar tissue nine months after operation, and Blachez found one seriously narrowed in three months; on the whole it is a much later complication than the others mentioned. Some cases are recorded where severe dyspnœa in adults was found to be due to a cicatricial band like a hymen stretched across the trachea at the seat of a tracheotomy done when a child. Mougeot, in a report to the French Academy of Medicine, advanced the belief that but few children who had had tracheotomy performed lived to adult life, alleging that they fell victims to obscure disorders the result of a tracheal constriction. In twenty years of inquiry he had never found a military surgeon who had seen a conscript with a tracheotomy scar, and he and all his friends could only recall six instances where tracheotomized children had reached adult life.

The diagnosis between the different conditions is far from easy. Trouble caused by a laryngeal polypus comes late, after the wound has been closed some days, as in Case II, above. The other conditions are apt to be present at the first removal of the tube. The trouble can be located as laryngeal or not by stopping the trachea tube; if air passes through the larynx the obstruction is tracheal, if not it is laryngeal. In Case I the trouble seems to have been due to collapse of the walls of the trachea when not held apart by the tube. The child was very young and the cartilages of the trachea very pliable, air passed through the larynx when the tube was stopped, and the collapse of the trachea walls could be seen when the tube was out and inspiration was attempted. Case II was a typical case of laryngeal polypus forming on the cicatrix in every respect. Case IV was undoubtedly due to the protrusion of granulations into the trachea, and Case III seems rather more like spasm than paralysis. The long duration, the clear voice, and the character of the recovery seems enough to exclude paralysis.

The prognosis in all these cases is at best rather doubtful. Ross [7] reported fourteen cases of polypi after tracheotomy (all that had been recorded up to 1883), and of these four had died before a second tracheotomy could be done, seven had a second tracheotomy (five of these recovered), and two had a third operation and were still wearing tubes. Of twenty-six cases of granulation obstruction collected by Koch [8] five died of suffocation, five wore a tube permanently, or at least many years, and seven got well. The remainder were uncertain. In forty cases from all the causes where a tube had been worn at least two months, collected from the journals and monographs, sixteen were fatal, nineteen cured, and five were still wearing tubes. The proportion of fatal cases is undoubtedly too large, as many cases were merely reported for the sake of the autopsies. The cure was often delayed for years, and the ages of the children in nearly all the cases was from two to four years, one was five and one nine years old. As to the frequency of its occurrence it would be hard to speak; it is evidently a rare complication, and I doubt if there are seventy-five cases on record. Its ætiology is altogether obscure and it is impossible to say in advance which case will offer difficulty in this respect.

The treatment has been as varied as it has been inefficient; here and there some therapeutic proceeding has been followed by a cure, but there will be two other cases where the same thing has failed. The German way is to open the trachea and remove any obstacle that may be found and cauterize the granulations. Other methods have consisted in the passage of bougies and drainage tubes and laminaria tents through the larynx to overcome its spasm and to dilate it. The most rational and by all means the most successful mode of treatment has been the abolition of a fenestrum in the tube and the substitution of smaller and smaller tubes, combined with patient waiting. A large number of the recorded recoveries have been spontaneous, often after the trial of ever so many different treatments and the abandonment of them all. Cauterizing and astringent applications to the granulations has been rarely productive of a cure. Where the trouble is of a mental character of course the indications must be met by suitable treatment.

The complication is altogether a trying and a treacherous one, and the obscurity of the whole subject adds much to its difficulty.

REPORT OF PROGRESS IN GYNÆCOLOGY.

BY F. H. DAVENPORT, M.D.,
Assistant in Gynæcology, Harvard University.

CURABILITY OF CANCER OF THE CERVIX UTERI BY OPERATIVE TREATMENT.

A RECENT debate on this subject in the Obstetrical and Gynæcological Society of Berlin, influenced Dr. M. Hofmeier,[1] by new and careful inquiries, to complete the table which he published some two years ago, in order to get at as complete as possible an idea of the ultimate results. His statistics differ from most others in that he gives the percentage of recoveries in the number of operations done up to a given time, excepting both those who died immediately after the operation, and those of whom nothing could be found out. That gave, of one hundred and forty-five operations, one hundred and seventeen which could be made use of, as twenty died from the effects of the operation, and eight could not be found. The following table shows the results:

1 Year.	Part Ext. 88.	Recurrence, 43.	Cured, 45 = 51	%
	Total Ext. 29.	" 15.	" 14 = 48	"
	Whole Number, 117.	" 58.	" 59 = 50	"
2 Years.	Part Ext. 68.	" 37.	" 31 = 46	%
	Total Ext. 25.	" 19.	" 6 = 24	"
	Whole Number, 93.	" 56.	" 37 = 40.2	"
3 Years.	Part Ext. 49.	" 26.	" 23 = 47	%
	Total Ext. 14.	" 12.	" 2 = 14.5	"
	Whole Number, 63.	" 38.	" 25 = 40	"
4 Years.	Part Ext. 29.	" 18.	" 11 = 38	%
5 Years.	Part Ext. 17.	" 11.	" 6 = 32	%

The percentage of cures, according to this table, falls from fifty per cent. after the first year to forty per cent. after the third year, which is to be attributed to the total extirpations, the percentage of cures after this operation falling from forty-eight per cent. to fourteen.

The lower percentages in the fourth and fifth years are not to be attributed to late recurrences of the trouble, but to the fact that at that time the indications for the operation were much less accurate. Hofmeier thinks the poorer results after total extirpation are due to the fact that the form of disease for which this operation is indicated comes later under observation.

Comparing these figures, however, with the results in carcinoma in other localities, they make a very favorable showing. The best results in Billroth's clinic were the cases of cancer of the face, with forty per cent. cures. Inasmuch as the percentage of cures following the supra-vaginal amputation remains about the same for those operated on one, two, or three years previously, compared with the whole number of operations, namely, forty-five per cent., one can conclude that certainly half of the cases which seem suitable for the operation can be cured.

Local return of the disease more than a year after operation is very rare with what he calls cancroid of the vaginal portion, and even then, is always in the cellular tissue. Five cases of late recurrence (four to five years) came under observation, two with completely healthy uterus, as confirmed by autopsy, and in the other three, as far as could be clinically determined, the uterus was free from disease.

In only four of forty-five cases was there local return of the disease after a year had elapsed, and in these cases the condition was suspicious, even before a year had passed. Hofmeier therefore concludes that if a year after operation there is an entirely normal condition, probability of local recurrence is only slight. In only two cases was the return of the disease so limited to the uterus that total extirpation was advisable. One died, and but four months had elapsed since the second had been operated on.

A SIMPLE METHOD OF TREATMENT OF CHRONIC UTERINE CATARRH.

Dr. Kugelmann[2] having found, by personal experience, and that of others, that finely-powdered iodoform snuffed up into the nasal cavity would cut short a nasal catarrh, was led to try similar treatment in cases of chronic endometritis. He uses a slight modification of a male catheter, with the blunt end filled out. Having placed a certain quantity of iodoform in the catheter, it is given the appropriate curve, well oiled, and introduced into the uterine cavity. The external end is then connected with a bulb syringe, and the powder blown into the uterine canal. The catheter is then thoroughly disinfected and dried. If several patients are to be treated the same day, a fresh catheter is needed for each one.

The author has treated numerous patients in this way without any unpleasant consequences. He recommends two applications a week, and has often seen marked improvement after a few treatments. He says, in speaking of its use in the nose, that Calabar Bean deodorizes the iodoform.

CURETTING THE UTERUS FOR THE REMOVAL OF PRODUCTS OF CONCEPTION.

Dr. Felsenreich,[3] in this article, begins by referring to the greater ease and safety with which abortions are treated now, owing to the use of the aseptic tampon. This results more often than formerly in the complete emptying of the uterus. In the great number of abortions, however, there still remain many where the retention of products of conception gives rise to dangerous hæmorrhages, and other unpleasant consequences. The author therefore gives some rules for simple operative procedures, such as can be carried out without assistance, and by the general practitioner. He operated alone in nine out of twenty such cases.

The symptoms which call for operative interference are hæmorrhage, decomposition of the contents of the uterus, and later, local inflammation or general constitutional infection. The question naturally arises, how long to wait if none of these symptoms appear. In exceptional cases, portions of the placenta may be retained and nourished for weeks, and even months, and the author gives details of a case where a portion of the placenta was expelled three months after an abortion without any signs of decomposition. He is of the opinion, however, that it is unwise to wait longer than two days, since after that time the retained products rarely come away spontaneously, and every hour of delay adds to the probability of hæmorrhage or infection. Should the physician not be within convenient distance of his patient, it is well to remove the placenta after a delay of a few hours only.

Of the methods to be employed, the first to be considered is the digital, for with the softened cervix it is the easiest, and gives us the greatest security that all has been removed. To this end, it is necessary that the

[2] Allgeimene Wiener Med. Zeitung, No. 42, 1885.
[3] Allgeimene Wiener Med. Zeitung, No. 44, 1885.

exploring finger should reach the fundus of the uterus, and it is important to see that the bladder is empty. Antiseptic intra-uterine injections before and after, and an iodoform tampon are the best preventatives of infection.

When the cervix is too narrow to admit the finger easily, it can often be accomplished by drawing down the uterus with the vulsellum. Schroeder has recommended for such cases the division of the cervix on both sides up to the vaginal insertion, with its subsequent closure by sutures. This is an operative procedure which hardly seems necessary. Slow dilatation by means of tents he considered dangerous, from the additional liability it affords to septic infection.

LACERATION OF THE CERVIX AND TRACHELORRAPHY.

This subject has, in England, only very slowly received the recognition which it deserves. It is therefore all the more gratifying to find its necessity so thoroughly appreciated, and its indications so clearly stated as they are by Dr. Grailly Hewitt in a lecture published in the *British Medical Journal* for January 2d, 1886. He first gives brief histories of eleven cases in which he performed the operation, and then gives his views as to symptomatology. The conclusions at which he has personally arrived are expressed in the following summary: "The operation is indicated by the presence of a chronic extensive eversion of the cervical lining; by the presence of considerable hypertrophy of the cervix, the result of laceration, and the more so if hypertrophy and laceration be conjoined; by the presence of chronic, severe local pain, evidently traceable to the irritation of a raw surface less extensive in amount, or traceable to cicatricial hardening at the bottom of the fissure; by the association of marked laceration, with a troublesome displacement of the body of the uterus; by the recurrence of repeated miscarriages in a chronic case; by the presence of an extensive recent laceration, even in cases where no severe symptoms have had time to develop, with the view of preventing (1) cellulitis; (2) the occurrence of cancer; (3) the supervention of symptoms generally; lastly, by the presence of general severe prostration, difficulty in locomotion, etc., obviously traceable to laceration."

The same subject was also treated of in a paper read before the British Gynæcological Society by Dr. R. T. Smith, and reported in the same number of the *British Medical Journal*. He had performed the operation in more than fifty cases, in which he considered the lesion the essential cause of chronic uterine affections, of protracted discharges, of periuterine inflammation, and of other serious disorders. He had operated on several patients from forty-seven to fifty years old, where there had been tenderness, menorrhagia, and various neuroses, with almost immediate and permanent relief. He operated in all cases of laceration in which there was any family history of cancer.

ETIOLOGY OF RETROVERSIO FLEXIO.

Dr. Harrison[4] considers the explanations of the mechanism of the production of retroversio-flexio as usually given in the text-books faulty. The two malpositions may be studied together, as they usually coexist, the versio being a transitory state, which develops into flexio. This condition may occur acutely as a result of increased intra-abdominal pressure, violence, etc., but is usually evoked by causes of a chronic character. Dr. Harrison does not share the opinion of the majority of gynæcologists, that retroflexion is rare in the virgin.

The first cause which he mentions is an arrest of development, which consists in an abnormally long portio-intermedia and short vagina, and especially a short anterior vaginal wall. The ordinary sequence of events is this: With these anatomical conditions when the bladder is full, such a uterus must lie in the axis of the vagina, and instead of a retro-positio, or displacement of the whole uterus bodily backwards, a retroversio is caused. This may became permanent from the supervention of inflammation or other cause, or, which is the more common event, a relaxation of the sacro-uterine ligaments occurs, which gives rise to retroflexio. These ligaments have been very carefully described by Luschka, and more recently by Küstner. If these become relaxed, the vaginal portio comes to stand forward, and the body of the uterus backward, and the emptying of the rectum and the filling of the bladder alter the relation of the uterus to the abdominal viscera, until intra-abdominal pressure affects the anterior, rather than the posterior surface, and the fundus is forced into the hollow of the sacrum.

Parametritis posterior is a common cause of the weakened condition of these ligaments, as after the absorption of the exudation they lose their contractility and elasticity.

Another frequent cause of retroflexio is laceration of the cervix. Here, when the tear is deep, inflammatory processes are apt to be set up in the corresponding side, and usually end in cicatricial contraction. The broad ligaments fail to act freely, the uterus recovers its position of anteversion only slowly, and with a full bladder, instead of the position of backward displacement in toto, it rotates on its longitudinal axis, and hence is more easily pushed over into retroflexio.

He concludes with the proposition that neither prolapse of the vaginal wall, whether due to subinvolution or to loss of the perineum, nor a uterus in a state of subinvolution, is competent to exert such a traction as to cause retroversio-flexio, provided the ligaments that maintain the uterus in situ are performing their normal functions.

Reports of Societies.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. M. GREEN, M.D., SECRETARY.

APRIL 10, 1886, the President, DR. A. D. SINCLAIR, in the chair.

DR. J. G. BLAKE reported a case of

ALBUMINURIC RETINITIS.[1]

DR. H. W. WILLIAMS said that in a considerable number of cases, in his own experience, the prognosis of blindness occurring during pregnancy, and associated with albuminous urine, is nearly always favorable, in the absence of marked retinal lesions; although the loss of vision may be temporarily almost total. Recovery of sight may follow the parturition, or may be considerably delayed; the albumen meanwhile gradually disappearing from the urine.

[1] See page 49.

A similar loss of visual power, with a like favorable prognosis, may occur after childbirth, as in cases of excessive lactation. But where, during or after pregnancy, marked structural evidences of nephritic retinitis are disclosed by the ophthalmoscope, a favorable ultimate result of the concurrent renal disease is not to be anticipated; although, as is often true in other cases of albuminuric retinitis, intervals of amelioration of the symptoms, and even of improvement in the ophthalmoscopic appearances, may occur: and the fatal termination may be deferred for many months.

In the cases first referred to, induction of premature labor would be needless: in the last-mentioned conditions it would be of no avail.

Rarely, cases also occur, in which anæmic conditions of the retina, or of the brain, perhaps a consequence of flooding during or after parturition, are followed, within a few days, by partial or complete loss of vision, without showing at the time marked changes in the retinal circulation. Here the prognosis is less favorable for complete recovery of the functions of the delicate perceptive structures of the retina.

Dr. Williams has seen a few cases of another grave ocular lesion, sometimes a sequel of parturition: a purulent choroiditis and suppuration of the contents of the globe, from septic intra-ocular thrombosis. If the entire system is not fatally involved in the puerperal infection, only one of the eyes may be thus disorganized; and, in such case, evisceration of the sloughy contents of the eyeball should be done, as soon as the condition is recognized; as a means of relieving the intense suffering, and lessening the chances of further mischief.

Dr. C. E. Stedman said that optic neuritis was sometimes associated with non-puerperal uterine disturbances, and instanced the case of a young lady, sixteen years of age, who had never menstruated and who suffered with optic neuritis of the left eye with impaired vision: there was no albuminuria. After a time the catamenia appeared and re-appeared: the neuritis gradually faded away, and now at the age of twenty-two the patient sees perfectly well.

SALT INFUSION IN THE TREATMENT OF HÆMORRHAGE.

Dr. F. B. Harrington, present by invitation, said that the patient, whose case he had reported to the Society at their February meeting,[2] had entirely recovered and walked out a week ago. The catamenia appeared six weeks after labor. The breasts began to flatten immediately after the birth of the child. Dr. Harrington also referred to a paper he had recently read before the Boston Society for Medical Observation, in which he had tabulated a number of cases reported by others: of fifteen cases of uncomplicated hæmorrhage, fourteen recovered. He also pointed out that the infusion should not be performed too rapidly, on account of the danger of overpowering the heart.

Dr. Strong said that to be successful in restoring the proper volume to the circulation, one must generally use a large quantity of the salt solution: he thought failure was often due to the use of too small a quantity.

Dr. Blake said he had tried transfusion of milk twice, but with temporary relief only. The idea of the salt solution infusion is to give the heart something to work on; but to be of any value the amount should be large.

[2] Vol. CXIV, No. 9, page 197, of this Journal.

Dr. H. W. Williams said that this treatment was tried in the Cholera Hospital many years ago, and there was immediate improvement in a certain number of cases: the pulse improved and the sweating diminished; but no cases recovered.

Dr. Harrington thought that not much good was to be expected in cholera, general peritonitis, etc., although favorable results had been obtained in typhoid. But the most appropriate use of salt infusion is in uncomplicated cases of hæmorrhage, in which it is desired simply to add to the amount of fluid in the vessels.

CONGENITAL ANIDROSIS.

Dr. C. E. Stedman spoke of a case of eclampsia in which he gave one-third of a grain of pilocarpine and repeated it twice, but failed to produce perspiration: the hot-air bath was also ineffectual. He learned that the patient never sweat when well. The pilocarpine spent its whole force in the salivary glands. The paitent did well, although the child was lost.

Dr. Davenport said he had seen one such case, which terminated fatally.

Dr. Blake recalled Dr. Clarke's teaching, that it was necessary in fevers to bring the skin down to the sweating point, which is about 101° F., before sweating will take place.

Dr. Sinclair alluded to the peculiar feeling of the skin in those who do not sweat, akin to icthyosis.

Dr. Lyman said that some people never sweat, even in hot weather: such people suffer much more from the heat than those who perspire freely.

Dr. Harrington said there was a myxodematous condition of the skin glands in those who did not sweat.

A NEW NIPPLE-SHIELD.

Dr. Forster showed Davidson's patent, duplex nipple-shield, which possessed certain advantages over other patterns.

THE USE OF PERMENGANATE OF POTASH IN AMENORRHŒA.

Dr. Lyman asked what results members had had with this method of treatment: he had himself employed it very unsatisfactorily.

Dr. Strong said that he had used it largely a year ago with out-patients, but had been able to follow up the cases in only a few instances, and therefore his results were rather limited. He believes that the drug is of no value where there is a deficient development, nor again in anæmia, but is more efficacious than any other drug when the patient is run down: he prescribes two grains four times a day, taken one hour before meals and followed with copious draughts of water. Many patients cannot take the drug before meals, and many receive no benefit from it whatever. He does not believe it has any effect to cause abortion: one patient, who thought she was not pregnant, took it for two weeks without bringing on the flow, and she was subsequently delivered of twins at full term.

Dr. Forster had used half-grain doses of permanganate for months, and with very good results.

Dr. J. Stedman thought the drug might do harm, if long continued.

— Sir James Paget has been elected a foreign associate of the French *Académie de Médecine.*

THE NEW YORK ACADEMY OF MEDICINE.

STATED meeting June 3, 1886.

DR. C. C. LEE read a paper on

THE FUTURE INFLUENCE OF SURGERY AND SURGICAL RESOURCES UPON OBSTETRICS.

There was nothing more impressive in the history of medicine, he said, than the rapid inroads made by surgery within the last few years into a domain which had been hitherto regarded as one purely medical.

Having given a *résumé* of the history of obstetrics in general, he presented a view of what had been accomplished in this department from a surgical point of view, and spoke first of Cæsarian section. He described its history, its dangers, and the method of performing it; after which he spoke of the four modifications of it, suggested respectively by Franck, of Cologne, Kehrer, of Heidelberg, Sänger, of Leipsic, and Cohnstein, of Heidelberg.

Keher's plan is described as consisting of a transverse incision through the anterior convex surface of the uterus at the level of the *os internum*, of deep sutures for the muscular walls, and superficial sutures to secure immediate contract of the peritoneal borders, and of strict antiseptic precautions during the operation, combined with subsequent drainage of the abdominal cavity. In order to cover the line of incision with peritoneum, he directs that the latter be separated from the underlying muscle for nearly a half inch from the borders of the wound.

Sänger suggested that, after the removal of the child through the ordinary incision, and a temporary elastic ligature had been placed around the cervix, a narrow strip of muscular tissue should be removed by a section running at first parallel to the borders of the wound by diverging outward as the section approached the peritoneal surface. The peritoneum was next to be detached, and allowed to cover the expanded portion of the Y-shaped section. He then advised the introduction of deep uterine sutures to the inner border of the wound (avoiding, however, the decidua), with a second set of superficial sutures designed to secure the contact of the peritoneal borders. This principle of "subperitoneal muscular resection," as it is called, has been practised by Leopold, who found it necessary, however, to make certain modifications in its applications.

The method proposed by Cohnstein was to turn the uterus completely out of the abdomen, and open it from behind; but, so far as Dr. Lee was aware, it had never been attempted in actual practice.

Having quoted from Dr. Robert Harris, of Philadelphia, the highest American authority on the Cæsarian section, to show that the greatest danger about this procedure arose from the delay commonly made in resorting to it, Dr. Lee spoke of the substitutes which had been devised to take the place of Cæsarian section. The first of these was Porro's operation, ovaro-hysterectomy, involving the removal, after the performance of the Cæsarian section, of both uterus and ovaries. This was afterwards modified by Müller, who recommended that the uterus, after the enlarging of the abnominal wound, should be tilted laterally, and withdrawn outside the abdomen previous to section.

The other substitute for the Cæsarian section was laparo-elytrotomy, as suggested and successfully practised by Dr. T. Gaillard Thomas, in which the dangers of opening into the perineum and wounding the uterus are avoided by an incision along the upper edge of Poupart's ligament, lifting the peritoneum, dissecting down to the vagina, dividing the latter transversely, and then, having reached the cervix, extracting the child through the passage thus artificially created. Although the number of cases in which laparo-elytrotomy had been performed, was as yet comparatively small, the proportion of successes thus far had been much greater than had been met with either in Cæsarian section or the Porro or Porro-Müller operation. During his remarks on this subject Dr. Lee quoted a number of statistics, most of them being from Dr. Harris' recent article in the "International Encyclopædia of Surgery."

He next took up the matter of extra-uterine pregnancy, and showed what excellent results had been accomplished by the use of electricity in the earlier months of ectopic gestation, as first successfully employed by Dr. J. G. Allen, of Philadelphia. Having spoken also of the results obtained by elytrotomy and laparotomy in the later months, he went on to treat of lacerations of the cervix uteri due to parturition. Personally, he said, he had never been successful in securing union when he attempted to repair this lesion immediately after labor, and he knew of but one surgeon who claimed to get good results in this procedure. In a large number of cases which were left to nature no subsequent operation was required.

With regard to lacerations of the perineum, however, the case was very different. Here the advantages of immediate closure were so immense that he regarded it as a matter of great importance, and he said that he would now as soon think of leaving a parturient woman with an undelivered child in the uterus as to neglect to sew up a torn perineum. The omission to do this on the part of many practitioners was the source of much suffering and misery, which might have been avoided with very little trouble.

Notwithstanding the fact that operative surgery had already accomplished so much in the field of obstetrics, he felt confident that, judging from the triumphs of the last few years, the results noted would be still more satisfactory in the future.

DR. WM. M. POLK said that this was a subject in which he was especially interested. For a considerable period after he commenced the practise of medicine he ranked himself as strictly a physician. In the course of time he became an obstetrician; but he entered upon his work in the department of midwifery with the conviction that it was simply a branch of the physician's art. It was true, of course, that surgical procedures were to be resorted to occasionally; but the much the larger part of the field, he believed, was purely medical. This feeling was to a great extent due to the training which he had received, and especially to the teachings of Professor Fordyce Barker. After a short time, however, he began to appreciate the fact that there were certain points in obstetric practice involving surgical methods, which if, at the present stage of scientific progress in the profession a man were to neglect, he would soon be driven to the wall.

When the practice of midwifery began to be taken out of the hands of women, the obstetrician had to contend against opposition on all sides. He stood, as it were, between two fires, that of the physician, who

had become developed out of the apothecary, on the one hand, and that of the surgeon, who was the regular successor of the barber, on the other. It was, therefore, only recently that obstetricians had become alive to the domain which was in reality of vast scope. At one time vesico-vaginal fistula was almost as much a reproach to the profession as cancer; but at the present large numbers of women were perfectly relieved, who formerly would have been left to drag out lives of misery and suffering. But the pendulum once started, was apt to swing a little too far, and it was probable that to-day the obstetric surgeon was not infrequently a little too free with the use of his knife.

As to lacerations of the cervix resulting from parturition, he had seen many serious cases, the rent, perhaps, extending to the vaginal roof, recover perfectly under ordinary treatment, without any operation whatever; and his views on this point were quite in agreement with those of Dr. Lee.

In the English hospitals, more than in this country, obstetricians had had to fight their way surgically against the mere physician, and also to contend against the active opposition of those recognized as general surgeons. But the same had been true to a considerable extent here also, and he was happy to say that the obstetrician, notwithstanding the indifference manifested on the one hand, and the active opposition on the other, had now won for himself an enviable position. He need only point to the matter of abdominal section. Surgeons complained that we opened the abdominal cavity too often. It might be: but that was simply a side issue. Before the obstetricians of to-day lay the grandest problem that could possibly engage their attention, namely, that in connection with the Cæsarean section. He did not doubt that within the next ten years it would be possible to eliminate entirely from practice the most repulsive of all obstetrical procedures, the destruction of the life of the fœtus by craniotomy. When this had been accomplished there would have been achieved the greatest triumph ever won in surgery; and the honor of it would belong to the obstetrician.

Dr. Fordyce Barker said that he did not hesitate to accept the position to which he had been assigned by Dr. Polk. He had long since found out that it was useless to attempt to rival many of his brilliant confreres in the matter of surgical procedure, and therefore, not being a surgeon, he was compelled to get along the best way that he could. He regretted that he had not been able to arrive in time to hear the greater part of the paper of the evening, and therefore he would confine his remarks principally to the topic to which the latter portion of it was devoted, laceration of the perineum.

He was not inclined to accept any new proposition until time and experience had determined its real merits; and for a long time he had held his opinion in regard to the immediate operation for perineal laceration in abeyance. Some years ago, at a meeting of the American Gynæcological Society, a distinguished obstetrical authority had made the statement that any physician who did not close by primary operation, a rupture of the perineum occurring in his practice, was neglectful of his duty. He did not express any positive opinion in regard to the matter at that time; but he hesitated to accept this dictum as correct, and at the present time he was still less inclined to acquiesce in its sentiment.

Dr. Barker then made the announcement that in no case that he had ever attended in his private practice had a secondary operation been performed; and this was simply for the reason that it had never been required. He would not say that he had never had any perineal laceration; but only that none of them were of such a character as to demand a secondary operation. The uterus retained its position perfectly in every instance, and no other bad result occurred from the rupture. He could furthermore say that up to the past winter, in no private case of his had a primary operation been performed.

During the season just closed, from November 1, to May 1, there had been a peculiar epidemic in this city. In consultation he had seen forty such cases; but in his own practice only one had occurred. There were no symptoms till about the sixth day, when an explosion occurred in the system; the temperature rapidly running up to 104, 105, or 106. Only one, however, of the patients that he had seen, died. In the case of the others, the symptoms all disappeared, as a rule, within three days. Out of the entire forty, he was called to see only twenty more than once. It was a significant fact, he thought, that in five out of the forty cases, the primary operation for lacerated perineum had been performed; and in only one of these had union taken place. This was the case in which the patient died. In the one that occurred in his own practice there was some contraction of the pelvis, and he delivered the child from the superior strait with the Simpson modification of Tarnier's forceps. Here there was an extensive laceration of the perineum, and the primary operation was performed; but the union did not take place.

In two cases that he knew of, in which the primary operation was performed, there was profuse uterine hæmorrhage, as a result of shock. After referring to other cases, Dr. Barker said that his mature opinion was, that while there were, no doubt, cases in which the condition of the patient was so favorable that primary union was likely to result from an immediate operation, as a rule it was safer to avoid the operation and trust to absolute cleanliness and watchful care of the patient. He could not, therefore, accept the prevalent teaching of the day; and he was glad to hear Dr. Polk express himself as he did in regard to primary operations. If there was any tendency to septic trouble, he thought the immediate sewing up of the perineum would be likely to be attended with unpleasant consequences on account of the interference which was thus caused to free drainage.

Dr. Barker then went on to speak of the marked influence which the gynæcologist had had upon the surgery of the present time, and in this connection referred to the last paper which Dr. Marion Sims had read before the Academy, in advocacy of laparotomy in traumatic lesions of the abdomen; when the late Dr. James R. Wood, in a forcible address, had argued against this procedure on the ground that while the gynæcologist would carefully prepare his patient for the operation, the general surgeon would be called upon to operate suddenly, and under the most disadvantageous circumstances.

Dr. Malcolm McLean said that he felt compelled to advocate the desirability of the primary operation in lacerations of the perineum. He had found that in those cases in which he sewed up the laceration with soft silk sutures, the result was more satisfactory than

in those which were left to nature. He did not believe, however, in using silver-wire sutures, as they were apt to displace the parts; but silk sutures, deeply and carefully placed, were generally efficient and satisfactory, while they had the advantage, at all events, of never doing any mischief, even if they did not accomplish the desired result. Moreover, they served a good purpose by their moral effect in backing up the accoucheur in case union did not take place; for in these days when so much was expected of one in the way of operative surgery, a reflection was apt to be cast upon the medical attendant if he neglected to take proper care of a lacerated perineum. In the main, however, he had found this simple operation of decided practical advantage.

DR. H. J. BOLDT spoke against the primary operation in lacerations of the cervix. If repair did not take place by nature, he said it was easy to perform the secondary operation at any subsequent time that was convenient. He therefore would protest against the immediate operation, unless there was a profuse hæmorrhage which was due to the laceration of the cervix.

DR. POLK said that he wished to correct a misapprehension on the part of Dr. Barker. His remarks were made in reference to lacerations of the cervix, and not of the perineum.

In answer to an inquiry by Dr. Barker, as to what his present views were in regard to the primary operation for perineal lacerations, Dr. Polk said that he felt constrained to say that he entirely acquiesced in the opinions expressed by Dr. McLean. He would admit, however, that there were exceptions, in which the conditions so well described by Dr. Barker contraindicated the primary operation. There were many cases in which the accoucheur had had a bad operation, or labor had been unduly prolonged, where the exciting condition of shock would be likely to be followed by hæmorrhage; and here we were perfectly justified in declining to operate. We should always be sure that the patient had not already been subjected to the risk of shock before we made any attempt to repair the laceration.

Like Dr. McLean, he greatly preferred the silk suture, and it was now some time since he had abandoned the use of wire sutures in either primary or secondary operations of this kind. Silk, properly prepared and soaked in a bichloride solution before using, was quite as efficient as silver wire. It was natural that the latter should have been preferred to all others before the days of antiseptic surgery; but now that we could summon antiseptics to our aid, we were able to dispense with the metallic suture, which was always a cause of great pain and annoyance to the patient. The withdrawing of the sutures, also, was always attended with more or less suffering.

In closing the discussion, Dr. Lee said that he differed from Dr. Barker in regard to the advisability of the closure of perineal lacerations. It might be that he had not been able to place his patients under the same favorable conditions for spontaneous recovery which the latter had; but, at all events, he had not been fortunate enough to obtain the same satisfactory results when such cases were left to nature. He then referred to the practice observed in the lying-in department of the New York Foundling Asylum, in which the patients were nearly all primiparæ. In this institution it was the uniform rule in every case, whether the patient was attended by the house-surgeon or one of the visiting physicians, that immediately after labor the condition of the perineum should be ascertained, and if it were found to be decidedly torn, to close the laceration at once. Of course, he did not wish to be understood as advocating an operation when there was merely an abrasion, or a tearing of the fourchette, which is almost universally the case with primiparæ. He did not believe, either, in operating when there was profound shock present from loss of blood, or other cause; but he had very rarely met with such a condition in his practice.

The plan which he adopted was simply to continue the chloroform under the moderate use of which the child was born, and to make an examination of the perineum; when, if a decided rupture was found, the chloroform was further continued, and the laceration repaired by means of silk sutures. Like Dr. Polk, he had not in some time employed silver-wire sutures in either primary or secondary operations. If the posterior wall of the vagina was involved in the laceration, he usually put in two or three cat-gut sutures at this point. The whole operation was a very simple one, and he had never seen shock caused by it. He always performed it under chloroform. In his practice at the Woman's Hospital he had seen many bad results, which might have been avoided, which were the direct consequence of ruptures of the perineum which were allowed to go without operation.

Recent Literature.

Textbook of Ophthalmoscopy. By EDWARD G. LORING, M.D. Part I. The normal eye, the determination of refraction, diseases of the media, physiological optics, and theory of the ophthalmoscope. New York: D. Appleton & Co. 1886. 8vo. pp. 274.

Dr. Loring has, without doubt, done more to perfect the ophthalmoscope as an instrument of precision than any other ophthalmologist. This fact, together with his well-known accuracy of observation, bespeak for a textbook on the ophthalmoscope written by him more than casual attention. The book justifies our expectations. The language is clear, concise, and accurate. The arrangement of the book is methodical, and it is evident that care and thought have been spent in its construction. The work has all the freshness of an original treatise, and is a pleasing contrast to many of the hastily-compiled so-called text-books in medical literature.

The first two chapters are devoted to the methods of using the ophthalmoscope. The third chapter contains the anatomy of the fundus of the normal eye. This chapter is unique in English literature. Nowhere else is it possible for the student to find the minute anatomy of the optic nerve, retina and choroid so elaborately described in one work. In fact, so clear an idea of the parts could heretofore only be obtained by those who had free access to the library of a specialist; and the student of the future will encounter fewer difficulties in understanding what he sees in the fundus because this chapter and the one succeeding it have been written. The fourth chapter describes the fundus of the normal eye as seen by the ophthalmoscope. The appearances of the various parts as thus seen are

well described, and much attention is given to the description of anomalies, a subject too often slighted in text-books of ophthalmology. Dr. Loring has been wise to give much of this, the first part of his work, to the appearance of the normal eye-ground and its variations, for a lack of this knowledge is, in fact, the greatest obstacle that the learner meets in the use of the ophthalmoscope.

The fifth chapter gives the ophthalmoscopic methods of determining the refraction of an eye. The manner of estimating the refraction by means of the upright image is clearly and succinctly given, but when our author approaches the subject of the method of determining the refraction of the eye by retinoscopy, he seems to be entirely at fault. For the manner of procedure in this method of examination he quotes word for word a foot-note in Donders' classical work on the accommodation and refraction of the eye. That foot-note is an extract from a letter from Bowman to Donders, calling attention to the phenomena seen when a mirror is used as described therein. The manner of using the mirror there described is not the manner of using it in modern retinoscopy. The entire subject is then summarily dismissed in the following manner: "It still remains, however, in my opinion, the most difficult and least satisfactory of any of the methods of determining the refraction of the eye. . . . I would refer the curious, however, and those fond of optical problems for their own sake, to papers on the subject by etc., etc."

It would be no more absurd for an author writing an encyclopedic article on methods of communication by means of electricity, after giving an elaborate description of the telegraph, to dismiss the subject of the telephone somewhat as follows: "There is a means of conveying the human voice, somewhat imperfectly, by means of electricity, over long reaches of wire, but it still remains, in my opinion, the most vexatious and unsatisfactory of all methods of electrical communication, etc., etc." This omission of a procedure in common use and highly esteemed by most English and many American ophthalmologists, whatever might be the author's opinion of it, is strange in a book otherwise so carefully prepared.

In the succeeding chapter the examination of the eye by means of the oblique light and direct illumination by the minor is very clear in its minuteness of description. There is an appendix to the book containing a simple explanation of physiological optics, the theory of the ophthalmoscope, and a description of the ophthalmoscope devised by the author. The book is well printed, on excellent paper, and has a neat binding. It is well and judiciously illustrated by wood-cuts and diagrams; the colored plates are good, but the frontispiece is much the best piece of workmanship of this kind in the book. Taken altogether it is a book that bids fair to become classical. M. S.

Diseases of the Digestive Organs in Infancy and Childhood, with Chapters on the Investigation of Disease and on the General Management of Children. By Louis Starr, M.D., Clinical Professor of Diseases of Children in the Hospital of the University of Pennsylvania; Physician to the Children's Hospital, Philadelphia, etc., with colored plate and other illustrations. Philadelphia: P. Blakiston, Son & Co., No. 1012 Walnut Street, 1886.

This work on the digestive organs of children is presented to us in most excellent form both as to type and binding, and is a very attractive book. There is nothing especially original in the text and it at times falls short of what we would be lead to expect in a discussion of this important branch of pediatrics; it is however, valuable as stating succinctly what is good in the older books. Possibly the part where the analysis of milk is discussed is not so satisfactory as if the more modern analyses had been taken as a basis for the deductions which are made on this subject, but the chapters on "Investigation of Disease" and "General Management," add much to the value of the book. It is to be noticed that the author does not introduce into his nomenclature the term dyspepsia, classifying instead, the symptoms belonging to this set of cases under the general term catarrh.

Cutaneous Memoranda. By Henry G. Piffard, A.M., M.D. Third Edition. New York: Wm. Wood & Co. 1885.

The endeavor to present a consideration of cutaneous diseases, including syphilis, in 264 pages of 32mo, is an application of the homœopathic principle of infinitesimal doses, to the administration of knowledge, which probably induced the *Homœopathic Times* to say of a former edition of this book that it "Can have no superior." The classification used is a peculiar one of the author, which is based on that of Alibert. Pathology is neglected, as it is in most manuals, while the best thing in the book is the chapter on the treatment of syphilis, which is excellent.

Lectures on Syphilis. By G. Frank Lydston, M.D. Chicago: A. M. Wood & Co. 1885.

These are nine lectures on syphilis, given at the Chicago College of Physicians and Surgeons, in which the views taken of the nature of the disease and its treatment are for the most part rational and proper ones, presented in a commonplace manner.

The Student's Manual of Venereal Diseases. By Berkeley Hill, M.D., and Arthur Cooper, M.D. Fourth Edition. Philadelphia: P. Blakiston, Son & Co. 1886.

The object of this manual is "to place before the student, as concisely as possible, the main elementary facts relating to venereal diseases and their treatment" has been accomplished in 119 pages, 16mo, to which are added thirteen pages containing various therapeutic formulæ. The pernicious advice to administer mercury "whenever a patient has a hard based indolent sore with enlarged inguinal glands" is given, but in general the teaching of the book is good, although too condensed to admit of much perspective in the presentation of the subject.

Venereal Memoranda. By P. A. Morrow, A.M., M.D. New York: Wm. Wood & Co. 1885.

This is the aphoristical statement in 321 pages of 32mo, of the present knowledge with regard to the venereal diseases. The work is well done and it is the best of these "manuals," which are more useful in recalling already acquired and forgotten knowledge than for purposes of primary instruction. G. H. T.

— Professor Breisky, of Prague, has been appointed to succeed Professor Spæth as chief of the second clinic for obstetrics in the Vienna General Hospital.

Medical and Surgical Journal.

THURSDAY, JULY 22, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $6.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

THE DIAGNOSIS OF INFECTIOUS DISEASES.

THERE are no diseases in regard to which the general practitioner of medicine is more certain to be called upon to make a diagnosis than the ordinary infectious diseases, measles, scarlet fever, typhoid and typhus fever, diphtheria, etc. These diseases, it is sad to confess, are most of them endemic in all our large cities and towns. The physician may never see a case of perforating ulcer, of Dupuytren's disease, of Basedow's disease, but he is quite sure sooner or later — and sooner rather than later—to be called upon to say whether some patient has measles or scarlet fever or diphtheria; whether he has typhoid or typhus fever; whether variola or varicella is present, or whether a purpura and urticaria or some other non-infectious disturbance of nutrition and circulation is simulating some one of the infectious diseases.

When summoned for such a decision the responsibility of the physician, moreover, is not limited to the welfare of the individual patient, but the prosperity of a whole community and the lives of many fellow-citizens may be, and often are, dependent upon a correct decision being reached. A failure to recognize a case of essential anæmia is likely to do little harm except to the physician's reputation as a diagnostician, and very possibly not even to that; but calling scarlet fever tonsillitis, or hæmorrhagic small-pox purpura, or *vice versâ*, offers opportunity to consequences calculated to make the doctor wish he had chosen some other calling.

The differential recognition of a typical case of the infectious diseases is generally easy enough, especially if attending circumstances are carefully considered; and it is, perhaps, owing partly to this that they prove less attractive subjects of study and observation to medical students than rarer and less important forms of disease. But the exceptional variations from the type — as shown by the occurrence, for instance, of an eruptive fever without the eruption — are both sufficiently numerous and remarkable to amply repay and exercise professional curiosity and diagnostic skill.

Owing to vaccination with strict separation of the sick and to improved hygienic surroundings of the poorer classes, small-pox and typhus fever have happily become so rare that it may show no want of zeal or intelligence on the part of the young practitioner should he hesitate to pronounce a positive opinion in a given case of either of these diseases. In view of the possible evils to the community of a failure to announce a real case of small-pox or typhus fever, or of the possible penalties of the law falling upon himself as a result of a mistaken announcement of such a diagnosis, the physician — unless very confident of his own judgment — will be wise always to refer doubtful cases to local health officers, and will be fortunate if living where such health officers are competent.

At a recent meeting of the New York County Medical Association a paper was read by Dr. Edward G. Janeway on "Certain Points in the Diagnosis of some of the Infectious Diseases," a report of which will presently be published in the JOURNAL, containing useful hints and suggestions for the differential diagnosis of some of the infectious diseases, and especially of small-pox. The writer's experiences as a health commissioner of the city of New York and as a visiting physician of Bellevue Hospital, have particularly fitted him to speak with profit to his fellow practitioners on such a subject, with a knowledge of their strength and weakness, as well as of the difficulties and dangers they encounter. Instances of confusion between small-pox and measles, scarlet fever, purpura, and syphilis had all fallen under his personal notice.

These points are emphasized as of assistance in establishing a diagnosis in perplexing cases:

First, it is important to know the nature of the disease from which a case not itself possessing positive features has developed.

Second, should the patient have died, this may be done by an investigation of others exposed to the originating case, these having, perhaps, a milder and more characteristic type of the malady.

Third, the result of exposure to an uncertain or malignant case without positive features, may, in some instances be a proof of the nature of the disease.

GLYCOGENESIS AND GLYCOSURIA.

As we compare the phenomena of nutrition in the vegetable and animal kingdoms, we see that the saccharine group of ternary substances has a predominant part in both, and that metamorphoses in which sugar in some form is the principal factor are essential to all the vital and formative processes. The seed cannot germinate till the starch in its cells is transformed into liquid glucose to nourish the sprouting cotyledons and plumule, in which change, heat and force are evolved by breaking up of the sugar into simple elements: a portion of the undecomposed sugar passes by dehydration into cellulose, the substance of which the tissue of the plant consists. The subsequent

growth and development of the plant or tree is a continued repetition of this nutritive metamorphosis; insoluble starch, generated from the carbonic acid and water of the atmosphere by the chlorophyle of the leaf, becomes converted into soluble dextrine and glucose and carried in the sap to distant parts where it is reconverted into amyloid granules and stored away for future use in certain receptacles called by Sachs the "reservoirs of reserve materials (seeds, tubers, bulbs, roots, etc.); a part subserves immediate uses by being turned back into carbonic acid and water, or changed into cellulose and woody fibre.

No less important a rôle is played by this group in the animal kingdom, where, as in the vegetable, starch is converted into sugar before it becomes assimilable. In all mammals the placental blood contains sugar in abundance, and the tissues of the embryo are rich in amyloid principle, or zoamyline.[1] The amniotic liquid of cows during the first months of gestation was found by Prout to contain large quantities of sugar of milk and lactates, and Berzelius deduces from this fact the conclusion: "that the constituent principles of the liquor amnii are destined to be absorbed by the fœtus and to serve for its development, since the same substances are also found in milk."[2] Although, owing to the greater complexity of the animal organization it is not easy to designate all the uses and all the mutations of sugar in the animal economy, yet the calorifacient and force-producing properties of this aliment are universally recognized; there is reason to believe that the force manifested in muscular contraction is derived from the combustion in the muscular substance of a form of sugar; if, moreover, it is not clear how this hydrate of carbon can assist in the fabrication of cells and protein structures, the fact, nevertheless, is becoming acknowledged by histologists that sugar is a formative material of prime value and importance. "When we reflect," says Bouchard, "that all the sugar utilized by the tissues results from the transformation of hepatic glycogen, and that this liver-sugar may derive its origin from certain azotized substances, since in carniverous animals the blood and tissues contain a notable quantity of saccharine material, generated by the liver, it is natural to suppose that if the liver breaks up azotized substances to set free glycogen and then sugar, so also the tissues may reconstitute protein substances by combining sugar with some azotized radical."[3]

But the analogy between the plant and the animal in reference to this special subject goes still farther. As the plant stores up in special depots, such as the roots, bulbs, parachyma of the stem and cambrium, the sugar-forming material, to be a reserve fund for future use, so in the animal, during the first half of fœtal life (Robin), the lungs and muscles subserve the same purpose; afterwards, this function is performed by the liver, which becomes the reservoir *par excellence* of amyloid substance. This amyloid substance, like starch, is insoluble, and its reactions to iodine are similar to those of starch; under the influence of a ferment peculiar to the liver, it undergoes transformation into glucose, and is the source of all the utilizable sugar of the economy.[4] Bernard called this peculiar amyloid matter glycogen, and into this substance all the saccharine products of digestion must be converted before they are available for the uses of the organism. According to the experiments of Pavy (Guy's Hosp. Rep., 1859), sugar is generated in but feeble quantities at a time by the liver, being delivered over to the economy as it is wanted; the relative proportion of sugar in the blood to the whole mass of that liquid, according to the estimate of Bouchard, is as 1.30 to 1,000 for arterial, and .90 per 1,000 for venous blood. The mass total of the blood of a man weighing sixty-five kilograms will lose one gramme of sugar in passing from the arterial to the venous state.

According to the observations of Claude Bernard, the formation of glycogen by the liver is intermittent, alternating with the production of bile. The sugar is formed during digestion; the bile, on the contrary, is produced during abstinence, flowing into the gall bladder and intestine. (These observations were made on snails).[5]

When the quantity of sugar generated in the liver and absorbed by the blood of the hepatic veins exceeds 3 per 1,000 of the whole mass of the blood (Lehmann), it passes into the urine; in other words, glycosuria results. It is, in fact, pathologically certain that the liver may, under certain circumstances, manufacture more glucose than can be appropriated by the economy, and this excess is eliminated by the kidneys.

Although there is still much obscurity as to the precise relationship of the liver to saccharine diabetes, and although profound pathologists like Bouchard look upon this disease as fundamentally a vice of nutrition in the tissues which normally appropriate sugar, yet for all practical purposes, and till better informed, we cannot go far astray in considering glycosuria (with Longet and Lecorché) as a functional perturbation of the liver. The fact that the liver may become subsequently the seat of inflammatory lesions does not militate against the view that glycosuria or diabetes is primarily, in the words of Lecorché, "a neurosis of the liver, in virtue of which the glycogenic functions of this organ are augmented."[6]

Lecorché, (who has lately written a very able work on Diabetes) shows conclusively that this functional disturbance may be of central origin (brain, medulla, etc.), and here Dickinson has pointed at the frequent concomitance of cerebral lesions with diabetes, or it may be of peripheral origin and result from disorder of the hepatic circulation by an obstacle to the respiration, by compression of the liver by direct or reflex irritation of the vaso-motor nerves. (Schiff). The production of artificial diabetes by the introduction of

irritating substances (ether, chloroform, turpentine) into the blood of the portal vein, seems to Longet to favor this view, and he adds that, "as for the influence of irritation of the pneumogastrics of puncture of the floor of the fourth ventricle on the production of the sugar by the liver, Bernard himself refers all these effects to a common agency, to the reflex excitation of the vaso-moter nerves of the liver, and to the active congestion of the hepatic vessels resulting therefrom: the more abundant afflux of blood to the organ, the greater activity of nutrition, the increased production of sugar are thus three correlative terms. The puncture of the cord *below* the phrenic nerves slows the abdominal circulation, the vessels of the liver contain less blood, the temperature falls, nutrition is retarded, and sugar production is reduced to a minimum."

It is believed that most (if not all) of these facts, experimental as pathological, which have a bearing on glycosuria, will fit into the above theory, which, as before said, makes of diabetes a functional disease of the liver.

AN ISLAND SANATORIUM FOR CHILDREN.

THE opening of the new sanatorium at Lowell Island deserves more than a passing comment. Although the list of our charitable institutions is a large one, yet there has been hitherto organized no attempt to afford the treatment of sea-side air for the class which may be termed the scrofulous and rachitic. The Sea Shore Home has devoted its accommodations and means chiefly to the more urgent care of young children whose death-rate in our heated months is so great from intestinal disorders.

It is well known that in many of the continental countries, sea air is looked upon as almost a panacea for that class of disorders of nutrition which is shown in the disorders of joints and bones.

In France is the famous Hospital at Borck, in parts of Germany the Baltic is utilized, and in Italy the Adriatic and Mediterranean afford ample opportunity for the fresh sea air so needed by the poor, crowded in the narrow streets and wretched buildings of the Italian cities and towns. England has, in a measure, used her coast for the same purpose.

The class presenting such disorders in continental cities has been a relatively large one, but it is only within a comparatively short time, since the influx of a large foreign poor class, that there has been any necessity for such care in our own country. The native American population is almost entirely free from rickets and though not exempt from the tuberculous joint-affections, yet they have as a rule been able to give the requisite care for such cases without organized help.

At the present time, however, our large cities contain besides a very large contingent of Irish and Irish Americans, (a class comparatively free from rachitic disorders, but not from the tuberculous affections), many Italians and Portuguese, among whom rickets is quite common. Furthermore the conditions of our increasing cities favor the development of such disorders.

The difficulty of utilizing our sea coast for such a sanatorium as has just been opened, is chiefly a climatic one. The sea shore summer on our coast is a short one, involving in such an institution, necessarily a large amount of expense *per capita* and a short time of activity. It is for this reason that the managers of the Convalescent Home for the Children's Hospital placed their institution twenty miles from the coast on high land, in a place where the season is longer, if not as free from July heat. This plan has also been followed by the Massachusetts General Hospital in their Convalescent Hospital at Belmont.

In adopting the sea coast plan for their Institute the managers of the Lowell Island Sanitorium were influenced by the generous offer of the Island fully equipped for a summer hotel, and also by the hope that the beneficial effect of sea air would be especially manifest in children suffering from chronic malnutrition, a belief which is entertained by all medical authorities.

It is to be hoped that the financial support of the Lowell Island plan may be such as to justify its continuance.

MEDICAL NOTES.

— An exhibition of the usual phenomena of hypnotism by a Signor Donato, which has been attended by a good deal of popular interest and excitement in Milan, has revealed the fact that the Italian authorities have the power, apparently, of putting a legal veto on all such proceedings, if they are pronounced injurious to the subjects of the experiments by medical or scientific experts whom the authorities consult. According to the *British Medical Journal*, the Prefect did thus put an end to the performances of Donato, on the passing of a motion by the Medical Society of Milan, that the experiments were injurious to the nervous systems of those who submitted to them, and referred the matter to the central authority at Rome, who consulted the Upper Sanitary Council of the Kingdom. Baccelli, the President of the Council, having requested and obtained permission to summon some of the leading Italian physiologists and psychologists to the assistance of the sanitary members, a meeting took place, and a resolution was passed to the effect that, for the protection of the liberty of every person, it was essential to prevent experiments which, while abolishing the consciousness of actions, produce morbid psychical effects on predisposed persons, and render them subject to the will of others. The Council says that public displays of hypnotism must produce great disturbance in the nervous susceptibilities of the spectators, and maintains that physiology and clinical experience offer decisive proof of this assertion. It is certain that the Government will empower the local authorities to act on this opinion, and that such experiments as Donato's will be no longer tolerated in any Italian city where the Prefect, or his representative, thinks it worth while to interfere.

— A veracious newspaper story comes from the West of a man, who, in a fit of despondency, swallowed a bottle of somebody's hair restorer, and on his death with obscure symptoms some years later, the whole abdominal cavity was found to be lined with a thick growth of hair, attesting the unfailing action of the hair persuader; which sounds like the chestnut regarding a kindred remedy, which, being accidentally spilled on the floor, produced a door-mat.

BOSTON.

— The Board of Health has finally voted to pass without disinfection a cargo of rags detained at quarantine since May, 1885, the disinfection of which has been a *casus belli* between the Board and the importers during all these months.

— Two cases of yellow fever were removed to the quarantine hospital lately from the forecastle of a brig which had visited the ports of Ponce and Miragoane, Porto Rico. The first case made its appearance when three days out, and the second when eight days out. The brig was detained at quarantine for fumigation and general cleaning.

NEW YORK.

— It was stated July 16th, that the rabbits which were inoculated by virus taken from the dog which bit the son of Dr. Newell, of Jersey City, who was recently treated by the Pasteur method by Dr. Valentine Mott, are dying of hydrophobia. Young Newell has as yet remained perfectly well, though the wound made by the bite has been somewhat slow in healing.

— During the week ending at noon July 10th, 1,111 deaths were reported at the Bureau of Vital Statistics, an increase of 203 over the mortality of the corresponding week last year. This large death-rate is directly attributable to the hot weather, and 683 out of the total number of deaths reported, were among children under five years of age. On July 9th, the highest mortality during the week, was reached, namely, 221.

Miscellany.

SCIENTIFIC ADVANCE IN THE TREATMENT OF TUMORS OF THE BRAIN.

Experimental research is constantly adding to the resources of the curative art, and is aiding to achieve new triumphs over diseases hitherto beyond reach. A correspondent writes: In a paper read before the Royal Society on June 10th, Dr. C. E. Beevor and Professor Victor Horsley, F.R.S., gave the result of an experimental investigation of the functions of that area of the cortex of the brain, which Dr. Ferrier showed to be the centre for the movement of the upper limb. They found that, when the upper part of this area was stimulated, the movements which followed commenced in the shoulder; that, when the lowest part was stimulated, the movements commenced in the thumb; and that, when the intermediate part was stimulated, the movements commenced in the wrist. These phenomena will be seen to be in agreement with the observations on the priority and the "march" of movements made by Dr. Hughlings Jackson in the particular type of epilepsy to which his name is often applied. It was not long before an occasion arose for applying the knowledge gained by these experiments to the cure of disease. A man was admitted into the National Epileptic Hospital (to which both Dr. Beevor and Mr. Horsley are attached), suffering from Jacksonian epilepsy, by which he had been incapacitated for two years. The fits began in the thumb; and Dr. Hughlings Jackson, under whose care the patient was, believed that the case was one to which the new knowledge with regard to the situation of the centre for the thumb might be applied, although the symptoms diagnostic of tumor were very vague. Owing to the great difference in complexity between the brain of the monkey and of man, there was, when the investigations of the functions of the cortex of the brain were first undertaken, considerable difficulty in applying the results obtained. At the present time however, these difficulties have been almost completely overcome, and the relation of the cranium to the subjacent convolutions has been thoroughly worked out. Mr. Horsley, therefore, although the patient presented no external signs of disease, and the skull had not been injured in any way, was yet able, by measurement, to apply his trephine over the cortical area which contained the thumb-centre. On removing the piece of bone cut out by the trephine on its first application, a tumor was detected immediately beneath. The hole made by the trephine was enlarged, and the tumor, together with the rest of the thumb-centre, was freely excised. As in the case to which reference was made a fortnight ago, Mr. Horsley treated the wound on precisely the same principles as those which he had found to be successful with monkeys after experimental operations, and the result has left nothing to be desired. The operation in this second case was performed on June 21st, and the wound healed by immediate union, so that on June 26th there was only a very small granulating surface, where drainage had been maintained. We find, on inquiry, that a week after the operation, the man was quite well, had had no fits, and was recovering power in the paralyzed limb.— *British Medical Journal.*

HOMŒOPATHIC TREATMENT OF MORAL INSANITY.

It may interest our readers to read of the definiteness of aim with which the homœopathic practitioner approaches the treatment of moral insanity. In the *Hahnemannian Monthly*, the following, among other therapeutic lists, are given for meeting the whole range of manifestations of this malady:

"*Hatred of work:* Spongia. *Arrogance:* Alum, Arn., Chin., Cupr., Fer., Hyosc., Ipec., *Lach.*, Lyc., Paris., *Platina, Stram.*, Verat. *Cruelty:* Anacardium, Crocus, Opium. *Cursing:* Anacardium, Corall. rubra, Lycopod., Nitric acid, Nux, Pulsatilla, Veratrum, *Fault-finding:* Ars., Ipec. *Want of religious feeling: Anacardium*, Colocynthis. *Hard-heartedness: Anarcardium*, Crocus. *Inhumanity:* Anacardium, Opium. *Kleptomania:* Ars., Bryo., Kali carb., Lycopod., Nux, Puls., Sep., Sulf. *Malice: Acon., Anacardium*, Ars., Bell., Canth., Caps., Carb. an., Chin., Cupr., Guaj., *Hyosc., Lach.*, Mosch., Nitr. acid, Natr. carb. Nux., Paris., Petrol., Plat., *Stram.* Moral feeling, want of: *Anarcardium*, Bismuth, Conium, Hyosc.,

Lauroc., Opium, Sabad. *Murder, inclination to:* Ars., Chin., *Hepar, Hyosc.*, Lach., Stram. *Slanderous disposition:* Ammon. carb., Anacardium, Ars., Bell., Borax, Hyosc., Ipec., Lycopod., Nitr. acid, *Nux*, Petrol., Sep., Stram., Veratr. *Mental derangements from alcoholic liquors:* Ars., Bell., Carb. v. Chin., Coff., Digit., Hell., Hyosc., Lach., Merc., Nitr. acid, Nux, *Opium*, Puls., Stram., Sulf."

"Clotar Mueller, in his most excellent repertory, gives:

"*Maliciousness:* Canth., Carb. an., Coff., Mosch., *Niccolum*, Nux, Petrol., Phos.; with destructiveness: Mosch. *Great obstinacy: Calc., Carb. Easily angered:* Mangan. acet., Sulf. *Cursing:* Bell., Borax, Hyosc., Lycopod., Nitr. acid, Nux, Plumb., Stram., Verat., Magnes austr. *Loss of feeling: Anacard., Opium, Stram. Homicidal desire:* Ars., Cann., Hyosc., Sec. cor., Stram."

We await with interest an improvement in the already exceptional virtue of the inhabitants of that region where the State of Massachusetts has expended so large a sum of money for the introduction of this treatment; for it is not to be supposed that the influence of these remedies will be expended entirely within the walls of the asylum in which they are administered.

It has been noticed that in some of our public institutions where *spongia*, as an outward application, is strongly indicated, there is a well-marked hatred of work. But the curative influence of the treatment has not hitherto been brilliantly successful. We trust that the internal application will not altogether supersede the external. In the same article, it is advised that, as hereditary moral obliquity is, in most cases, due to alcohol, it might "be advisable to fight fire with fire, and give our patients a very high potency of alcohol." The popularity of this treatment will evidently depend on whether or not the high dilutionist carries the day.

HEADACHE IN SCHOOL CHILDREN.

PROF. N. J. BYSTROFF has examined 7,478 boys and girls in the St. Petersburg schools during the last five years, and found headache in 868, that is, 11.6 per cent. He states that the percentage of headache increases almost in a direct progression with the age of the children, as well as with the number of hours occupied by them for mental labor; thus, while headache occurred in only five per cent. of the children aged eight, it attacked from twenty-eight to forty per cent. of the pupils aged from fourteen to eighteen. The author argues that an essential cause of obstinate headache in school children is the excessive mental strain enforced by the present educational programme, which leaves out of consideration the peculiarities of the child's nature, and the elementary principles of scientific hygiene. The overstrain brings about an increased irritability of the brain, and consecutive disturbances in the cerebral circulation. Professor Bystroff emphatically insists on the imperative necessity for permanently admitting medical men to conferences of school-boards. Of palliative measures, he mentions methodical gymnastics, mild aperients, in well-nourished children, steel in the anæmic, bromides, inhalations of oxygen, and, in severe cases, a temporary discontinuance of all studies.—*British Medical Journal*, May 15, 1886.

Correspondence.

MAINE.

ONE of the most noteworthy of recent events in medical circles in this State was the celebration of the fiftieth anniversary of the entrance into practice of the venerable Dr. Hiram H. Hill, of Augusta. All through Maine Dr. Hill has been recognized for many years as a surgeon of rare ability, of great originality of resource, and of marked devotion to his profession. In any community he would have occupied an exalted position. That he is not known widely in other parts of the country is doubtless due to the fact that he has not put on record in the medical journals the principal results of his large experience and his fertile ingenuity. Unfortunately his modesty, perhaps associated with a dislike for the quill, has confined his fame within narrow limits; but, where it has extended, he has long been acknowledged to be a master-spirit, and it was peculiarly fitting that his associates should make a public demonstration of their respect and affection for their Nestor on the completion of his half-century of active work in medicine.

The arrangements were nearly completed before Dr. Hill was informed of the design, and, with characteristic shrinking from notoriety, he immediately endeavored to effect a stay of proceedings. But his friends were not to be denied the pleasure which they had anticipated, and on the 15th of June, a banquet was spread at the Augusta House, and physicians from far and near gathered to do honor to their eminent guest. There were present, also, many prominent gentlemen from other walks of life, and the assembly was truly representative of the best element in the community.

The dinner was very elaborate, the bills of fare were printed on heavy silk, and the tables were decked with a profusion of flowers. On the wall behind the aged surgeon who is now seventy-six years old, was an oil portrait, for which he sat nearly half a century ago. Dr. H. M. Harlow, of Augusta, for a generation the superintendent of the Maine Insane Hospital, presided, and Dr. A. P. Snow, of Winthrop, acted as toast-master. The toast to "Our Honored Guest," called forth a speech which recited in quaint phrase and with much dryness of humor the leading incidents of a medical career, which, in its fidelity to noble purposes, could well be taken as a pattern by any young man. It showed how the country lad, born with an insatiable desire for knowledge of natural history, studied the living beings around him without the guidance of books or master, learned much about their structure and functions without having names for their parts and processes, and struggled laboriously up from the position of office-boy to that of deserved prominence in the medical profession; and it was all told so simply and unaffectedly as to prove that genius and humility are by no means incompatible. Then came toasts with the following titles, responded to by the gentlemen indicated: "Fifty Years ago," by Hon. J. W. Bradbury, formerly United States Senator; "The Medical School of Maine," by Prof. Alfred Mitchell, of Brunswick; "The Physician and Surgeon as a Factor in the Administration of Law," by Hon. Artemas Libbey, Justice of the Supreme Court of Maine; "The Maine Medical Association," by Dr. A. J. Fuller of Bath; "The Maine General Hospital," by Dr. S. H. Weeks, of Portland; "The State of Maine," by Hon. O. D. Baker, the Attorney General; "The Surgeons of Maine in the War," by Dr. A. Garcelon, of Lewiston, formerly Surgeon-General of the State. The speakers all united in their testimony to the professional skill, the kindness of heart, the unswerving integrity, and the high standard of honor which Dr. Hill has always manifested. Judge Libbey dwelt particularly on the qualities which are necessary to make medical expert testimony valuable, and credited Dr. Hill with that soundness of learning, unbiassed judgment, unpurchasable honesty and candor of statement, which are often conspicuously lacking in alleged experts. The exercises concluded with the reading of a poem, written for the occasion by Dr. F. H. Gerrish, of Portland. The celebration was greatly en-

joyed by all present, and every one must have been impressed with the value of such social gatherings in the cultivation of good-fellowship. Dr. Hill is still actively engaged in practice, and enters on the second half century of his professional work surrounded by hosts of friends, and cheered by the love and reverence of the community in which he has spent a long and most useful life.

For some years efforts have been made to effect the removal of the Medical Department of Bowdoin College, often known as the Medical School of Maine, from Brunswick to Portland. The Maine Medical Association at its annual meetings has often expressed its desire in this regard, and the Bowdoin Medical Alumni Association has repeatedly taken action in the same direction; and it is proper to state that these votes have not been prompted by residents of Portland, but are the expression of the unbiassed opinion of physicians of other places. Last year both of these associations sent committees to the governing boards of the college to urge immediate action, and the entire medical faculty went before the boards to plead the cause of removal. The overseers were convinced by the arguments, but the trustees were not; therefore, favorable action could not be taken. This year further efforts were made, but with no better result. The principal reason for desiring a change is that sufficient clinical advantages are not possible in Brunswick, while Portland has the Maine General Hospital, the City Hospital, the Dispensary, and other facilities for the bedside instruction of students. The profession is properly demanding a hospital connection for every medical school, and none can long prosper in these times which does not heed the call.

There is no wish to remove the Medical School from the guardianship of Bowdoin College; none would deplore such a separation more than the members of the faculty, who fully appreciate the value of the prestige which sixty-six years of excellent work have given the institution. Already nearly all the members of the faculty reside in Portland, and it is obvious that they could do more satisfactory work if the school were to be removed to that city than is now possible, with their field of instruction nearly thirty miles away from their homes. The accommodation of the profession, however, is not at all a consideration; the good of the institution is what is kept steadily in view in seeking the proposed removal. That it will be effected within a few years there is very little doubt; but first a deal of timidity, of local prejudice, of unreasonable conservatism must be overcome in the board of trustees.

The annual meeting of the Maine Medical Association this year was marked with fewer incidents of interest than is usual. A number of creditable papers were read and remarkable cases reported. Dr. Frederick C. Thayer, of Waterville, pronounced a scholarly and attractive oration on the progress of medical science. The physicians of Portland gave an elegant entertainment to the out-of-town members at the Falmouth Hotel, which was much enjoyed. The principal officers for the ensuing year are as follows: President, Dr. J. B. Walker, of Thomaston; first vice-president, Dr. F. C. Thayer, of Waterville; second vice-president, Dr. H. E. Hill, of Saco; secretary, Dr. C. D. Smith, of Portland; treasurer, Dr. A. S. Thayer, of Portland; chairman of board of censors, Dr. M. C. Wedgwood, of Lewiston; orator, Dr. E. M. Fuller, of Bath.

REPORTED MORTALITY FOR THE WEEK ENDING JULY 10, 1886.

Deaths reported 3,367: under five years of age 1,887: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 1,146, consumption 354, lung diseases 258, diarrhœal diseases 882, diphtheria and croup 106, whooping-cough 31, typhoid fever 30, measles 28, scarlet fever 25, malarial fever 22, cerebro-spinal meningitis 12, puerperal fever seven. From typhoid fever, Philadelphia 10, New York, District of Columbia and Pittsburgh three each, Lawrence two, Brooklyn, Boston, Nashville, Fall River and Charleston one each. From measles, New York 14, Baltimore, eight, Pittsburgh two. Brooklyn, Boston, Cincinnati and Salem one each. From scarlet fever, Pittsburgh seven, Philadelphia six, New York five, Brooklyn and Cincinnati two each, Cambridge, Holyoke and Brockton one each. From malarial fever, New York seven, New Orleans six, Brooklyn, four, Baltimore two, Philadelphia, District of Columbia, and Charleston one each. From cerebro-spinal meningitis, New York six, Boston two, District of Columbia, Charleston, Worcester and Fall River one each. From puerperal fever, New York, Philadelphia, Boston, Cincinnati and Lynn one each, Pittsburgh two.

In the 18 cities and greater towns of Massachusetts, with a population of 918,161 (population of the State 1,941,465), the total death-rate for the week was 23.39 against 18.76 and 18.02 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending July 3d the death-rate was 17.6. Deaths reported 3,064: infants under one year of age 752; acute diseases of the respiratory organs (London) 197; measles 115, diarrhœa 86, whooping-cough 67, fever 30, scarlet fever 20.

The death-rates ranged from 13.3 in Salford to 30.4 in Preston; Birmingham 15.9; Blackburn 22.7; Bradford 17.8; Hull 18 3; Leeds 19.4; Leicester 15.7; Liverpool 18.2; London 15.8; Manchester 26.9; Newcastle-on-Tyne 21.9; Nottingham 18.7; Portsmouth 20.7; Sheffield 16.8; Sunderland 14.7.

In Edinburgh 19.7; Glasgow 24.2; Dublin 22.9.

For the week ending June 27th, in the Swiss towns, there were 49 deaths from consumption, lung diseases 16, diarrhœal diseases 14, measles 13, diphtheria and croup three, typhoid fever three, small-pox 2, whooping-cough and erysipelas each one.

The death-rates were: at Zurich 13.4; Geneva 11.1; Basle 16.6; Berne 17.0.

The meteorological record for week ending July 10, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, July 10, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 10, 1886, TO JULY 16, 1886.

PAGE, CHARLES, lieutenant colonel and surgeon. Leave of absence further extended one month. S. O. 156, A. G. O., July 8, 1886.

GIBSON, JOSEPH R., major and surgeon. Granted leave of absence for three months, to take effect about August 1st. S. O. 158, A. G. O., July 10, 1886.

WATERS, WM. E., major and surgeon. Ordered for duty as post-surgeon, Fort Spokane, Wash. Ter. S. O. 112, Department of Colorado, July 2, 1886.

GARDNER, EDWIN F., captain and assistant surgeon. Granted leave of absence for two months. S. O. 158, A. G. O., July 10, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING JULY 18, 1886.

WENTWORTH, A. R., assistant surgeon. Detached from the United States Steamship "Brooklyn," and wait orders.

NORTON, OLIVER D., assistant surgeon. Detached from the United States Steamship "Minnesota" and ordered to the United States Steamship "Brooklyn."

INFORMATION WANTED. ARSENIC IN SKIN DISEASES.

The Editor of the "Journal of Cutaneous and Venereal Diseases" is desirous of ascertaining to what extent arsenic is used by American physicians in the treatment of skin diseases, and also the results of their experience as to its therapeutical value.

Information upon the following points is requested of every physician who reads this:

Are you in the habit of employing arsenic, *generally*, in the treatment of skin diseases?

In what diseases of the skin have you found arsenic of superior value to other remedies?

What ill effects, if any, have you observed from its use?

What preparation of the drug do you prefer, and in what doses do you employ it?

Address, Editor of
JOURNAL OF CUTANEOUS AND VENEREAL DISEASES,
66 *West 40th Street, New York.*

IODOFORM POISONING.[1]

BY ELBRIDGE G. CUTLER, M.D.

I. In October, 1876, a lady about sixty years of age came under my charge with cancer of the uterus involving the upper part of the vagina in front and behind. The history was of over a year's duration. The patient was very feeble and confined to her bed. On examination the uterus was found to be fixed, and an indurated nodular crater of considerable size was discovered in place of the cervix. There was much foul smelling, sanguineo-serous discharge constantly, and considerable pain and occasionally hæmorrhage. After exhausting other resources she received suppositories of cocoa-butter containing five grains each of powdered iodoform, one every second day for twelve days (six in all) to diminish the pain and discharge and to change the character of the odor. After a few days the patient became somnolent, the pulse got high, she refused food, and emaciation set in. Soon somnolence gave place to coma, emaciation progressed and she died in collapse thirty-three days after my first visit, ten days after the last suppository. There was a little albumen in the urine (drawn by catheter) but plenty of urea. It was not until some time afterward that I believed that the iodoform had proved poisonous.

II. A few months ago in a congenitally neurotic patient, with post-partum diphtheritis of the vagina and uterus, I introduced six of Mitchell's iodoform uterine bougies, containing five grains each. One was placed in the afternoon of the first day, one morning and night of the next day, and one in the morning of each of the next three days. Within an hour of having the first bougie she complained of feeling faint, and having a bad taste in the mouth; the sensations recurred several times in the night. After the second bougie this faintness increased in frequency and was attended with nausea and vomiting. After the fourth she got despondent, tearful, melancholy, was sure she never should recover, and that her baby would die. There was nausea, anorexia, and profuse sweating, and she was very sleepy most of the time. After the fifth, she fainted several times, the pulse remaining, good, full, and about eighty in the minute. She took final leave of her friends preparatory to death, did not wish to recover, and once asked to be chloroformed immediately "and make an end of it." All this time she was getting along well in other respects. She vomited two or three times and slept the greater part of the day and night. After the sixth suppository the faintness recurred and the mental depression increased. As there was no longer any appearance of diphtheritis the iodoform was omitted and the symptoms gradually disappeared. The first to depart was the nausea, faintness and bad taste, afterward the sweating, and lastly the mental depression, which continued the longest. It was fully two weeks after the last bougie before all traces of its action had disappeared.

On a somewhat extended search I have found the following cases of poisoning recorded; they are all which were accessible to me. The first thirty were collected by Koenig, who was the first to make any extended observations:

[1] Read before Boston Society for Medical Improvement, May 10th, 1886.

(1) Man, aged eighteen, tuberculous abscess above the knee, opened. One gramme iodoform applied. After a few days appearance of symptoms. Delusion that he was being pursued, attempts to leave his bed. Recovery after a few hours.

(2) Woman, forty-seven, carcinoma of breast, amputation. Iodoform and iodoform gauze applied. Lister dressing. On the fourteenth day the first symptoms began; they were ill-humor, delusions. Recovery on the twentieth day.

(3) Woman, thirty-two, fistulæ in caries of the ileum, scraped out. Filled with iodoform. Symptoms seventh night, leaves bed, attempts to escape, afterward morose behavior and perverted answers to questions. Recovery (day not stated).

(4) Man, sixty-two, caries of foot, Pirogoff's operation. Iodoform and iodoform gauze, Lister dressing. Ninth day restlessness and anxiety, leaves bed, talks confused nonsense. Recovery on the seventeenth day.

(5) Woman, twenty-four, osteo-sarcoma of jaw, resection. Iodoform and iodoform gauze, then iodoform blown in for seven days. On the eighth day sleeplessness, anxiety, fear of being carried off. Gradual improvement after removal of iodoform.

(6) Man, thirty-five, extensive burn of skin. Every second day powdered with iodoform. On seventh day, "after two dressings," talked confused nonsense, absolutely sleepless, gets out of bed, tears bed-clothes. Recovery about the twenty-eighth day.

(7) Man, sixty-eight, tuberculosis in foot, amputation. Fifty grammes iodoform (in three dressings). Eighth day restlessness, gets out of bed. Rapid disappearance of symptoms.

(8) Man, forty-eight, fracture and dislocation of ankle-joint. Drainage of foot. Sixty grammes iodoform. Beginning on the eighth day there was for three weeks confusion, restlessness, getting out of bed, stupor. Recovery about the twenty-eighth day.

(9) Woman, seventy-two, senile gangrene. Sprinkled with iodoform (thickly). After a time (not stated) temporary lethargy, delirium, defective memory, hallucinations. Death in six weeks later.

(10) Woman, seventy-three, carcinoma of rectum, operation. Eighty to one hundred grammes iodoform applied, drainage. On the eighth day restlessness, recognizes nobody, does not know where she is, jactitation. Recovery in about four weeks.

(11) Man, sixty-eight, hypertrophied prostate, no operation. Suppository of iodoform and cocoa-butter, then iodoform-vaseline per rectum. Eighth day after using the salve, confusion, delusion of being pursued, gets out of bed, attempts at flight. Recovery "after a few days."

(12) Man, seventy-one, galvanocaustic amputation of penis. Sprinkling of the scab and eight days later the wound with iodoform. Twelfth night, boisterous, during the day refusal of food. Suicidal tendencies. Recovery after "four or five days."

(13) Woman, fifty-four, tuberculosis of foot, curetting of the medullary cavity of tibia. Forty grammes iodoform placed in the cavity. Lister dressing. On the eighth night, confusion and restlessness, afterward hallucinations and refusal of food. Recovery on the eighteenth day.

(14) Woman, twenty-two, ichorous ulceration of the knee-joint, amputation. Iodoform powder and iodoform gauze. Fifty grammes to the eighteenth day. On the nineteenth night attack of insanity, hallucina-

tions. Eight days later severer attack of insanity, distracted. After twenty-seventh day improvement (gangrene occurred later).

(15) Man, twenty-one, arm injured by machinery, at first conservative surgery, then exarticulation. At first forty to fifty grammes iodoform. After operation fifteen to twenty grammes. Two days after operation restlessness, confusion. A few days after the first application of the iodoform, anxiety, afterward insanity. Recovery fifteen days after the operation.

(16) Woman, forty-three, carcinoma of breast, extirpation. Fifty to eighty grammes iodoform. Lister dressing. Night following tenth day, restlessness, bad language, then insanity, distracted. Death on twenty-first day. (Erysipelas?)

(17) Man, sixty-one, arthritis deformans, resection. Iodoform eighty grammes. Ninth day restlessness, involuntary discharges, stupor, and on seventeenth day maniacal attacks. Death on twentieth day. Collapse, œdema of lungs.

(18) Man, seventy, tuberculous sequestrum of femur, extraction. Ten to fifteen grammes iodoform. Lister dressing. Ninth day delusion of being pursued. Afterward insanity. Death about the twenty-first day (in the third week after the outbreak).

(19) Woman, sixty-nine, extirpation of breast. Iodoform (quantity not stated). Healing by first intention after nine days. On tenth night restlessness, attempts at flight. Seventeenth day maniacal attacks. Involuntary discharges. Death on twentieth day. Œdema of lungs.

(20) Man, sixty-one, caries in knee, amputation. Iodoform and iodoform gauze, six days later twenty-five grammes iodoform. On the eighth to the tenth day restlessness at night. During the day sleep, pain; eleventh day hallucinations, afterward refusal of food, death on twelfth day. Collapse.

(21) Woman, sixty-seven, tuberculous elbow-joint. Resection. Ten to fifteen grammes iodoform. Lister. Fourteenth day restlessness, confused talk, refusal of food, afterward attempts at flight during the night. Twentieth day clearer consciousness. Death the twenty-first day. Œdema of the pia.

(22) Man, sixty-three, resection of upper jaw. Powdered with iodoform, the following day blown in. Seventh day restlessness, delusion of being followed, hallucinations. Death the twenty-eighth day. Pneumonia symptoms.

(23) Man, twenty-two, complicated fracture of the leg, large incision. Every three days dressing with about fifteen grammes iodoform. Fourth night sleeplessness, restlessness, anxiety; by day rational; loss of appetite, wretched appearance. Improvement after the omission of the iodoform.

(24) Woman, forty-six, struma, extirpation. Iodoform: Lister dressing on the fifth day. Second day repeated vomiting, pulse 164, later more vomiting. On the fifth day dyspnœa, great restlessness, confused talk. Death the sixth day. Œdema of lungs. Autopsy showed fresh pneumonic nodules.

(25) Boy, five, large abscess from coxitis, incision. Sixty grammes iodoform. (Day on which symptoms began not stated). For six weeks somnolence and great perspiration. Recovery after six weeks.

(26) Boy, six, periarticular abscess of the hip-joint, scraped with sharp spoon. Twenty grammes iodoform, then iodoform pencils daily. (Day not given). Apathy, tearfulness, thirst, vomiting, fever, bloody urine. Recovery on eleventh day. Daily change of dressing.

(27) Girl, fifteen, suppuration of hip-joint, resection. Thirty grammes of iodoform, from the fourth day. Lister. Second day vomiting, nausea. Third day flexion contractures. Fourth day sopor. Involuntary discharges. From the fourth day no improvement of the nervous symptoms. Later septicæmia and death.

(28) Boy, fourteen, cheezy abscess of the hip-joint, resection. "Coffee-spoonful" iodoform, iodoform gauze. Second day restlessness, fever, stupor, stammering, and vomiting, and on the third day unconsciousness. Death on the third day. Fatty liver and kidneys.

(29) Man, fifty-one, empyema. Every third day gelatine-iodoform pencils. Cross-grained, iodoform smell and taste, anorexia, dulness of head. Thirteenth night, insanity and insane ideas, getting out of bed. By day confounding of known people. Recovery on the sixteenth day.

(30) Man, forty, stretching of sciatic nerve. After sixteen days iodoform. After two days sleeplessness and increasing restlessness. Seventh to ninth (?) day insanity, getting out of bed. Recovery on the sixteenth day.

(31) Man, sixty-one, iliac sinus after operation for hernia, incision. Three days iodoform on lint, then blown in for twenty-one days. Third day emaciation began. Nineteenth day low feeling, anorexia, dull, heavy, drowsy, disinclined to move, wandering at night, emaciation. Twenty-third to thirtieth day tongue dry, brown, emaciation, pulse 130, temperature 101.6°, hebetude, exhaustion. Three weeks later recovery out of hospital. Iodoform omitted at discharge.

(32) Man, thirty-eight, extensive burn. Iodo-vaseline after four days. Second day pulse and temperature increased. Sixth day delirium, pulse 130, temperature 101.6°, weak. On tenth day restlessness, attempts to pull off bandages and bed-clothes. On following days symptoms continue, emaciation, temperature decreases, pulse increases and is feeble. Symptoms last till end of sixth week when coma came on. Death at end of seventh week. Autopsy shows petechiæ over left lung and posterior surface of heart, congested lungs and broncho-pneumonic nodules.

(33) Child, four, extensive burn. Iodo-vaseline on lint. Second day sleepless at night, screaming suggestive of meningitis; drawing up of legs, intense headache. Temperature 104.6°, pulse 160. Screaming continued, grinding of teeth, unconsciousness, extremely restless, eyes twitching and rolling during the next three weeks, rapid pulse. Iodoform then omitted. Recovery complete on the twenty-second day after omission.

(34) Boy, eleven, lumbar abscess, incision, caries of spine. Wall of abscess wiped out with a sponge filled with iodoform. Drainage tubes. Iodized wool dressing. Third night restlessness, rise of temperature (104.6°) and pulse 138. During the next two days vertical headache, drowsiness, nausea, smell of iodoform in breath. The wounds then washed out with carbolic wash and carbolic gauze substituted for iodoform gauze. Recovery by twenty-fifth day.

(35) Woman, adult, chronic inflammation of middle ear, local application. Small ball of cotton dipped in powdered iodoform and applied, reapplication after twenty-four hours, renewed in three days. Within twenty-four hours dizziness, drowsiness increasing to

fourth day to a very marked degree, pulse almost imperceptible, breathing very slow and superficial, fainting. Iodoform washed out. Perfect recovery on the second day.

(36) Man, sixty-two, white swelling of knee-joint, scraping out of fistulæ. Twenty grammes iodoform put in fistulæ. Iodoform wadding, changed on fourth and eighth days with fresh application of ten grammes iodoform. Ninth night delirium, pain in knee, temperature 101° nearly, iodine reaction in urine, urine passed in bed. Two days later completely unconscious, refused to swallow and bit teeth together on attempts to feed him, tightly closed eyes on attempts to open same, contraction of neck muscles on attempts to move head forward, forearms convulsively contracted, twitchings in arms, increase of pulse and temperature to 140 and 103° respectively, sopor. Death on the twelfth day. Autopsy shows lepto-meningitis and splenic tumor.

(37) Woman, fifty-eight, cancer of breast, amputation and removal axillary glands. Iodoform gauze dressing, six grammes iodoform dusted in the wound. Third day apathetic, complains of feeling bad on being loudly addressed, appetite poor, tongue coated. Iodine reaction in the urine intense. Increase of somnolence and apathy. Trembling movements of hands, attempts to brush things away from face, pulse 120 to 130, temperature normal. Anorexia, pupils do not react, restlessness, increasing weakness, sopor. Death twenty-three days after the operation. Pia injected, œdematous, fatty liver, cloudy kidneys.

(38) Man, eighty-two, carcinoma at angle lower jaw, removed. Four grammes iodoform powder covered with wadding. Second day very restless, excited, tries to get out of bed, answers only on loud calling, complains of great headache, thirst; next day unconscious, jactitation, muscular twitchings of face. Fourth day pupils contracted, pulse 130, temperature 100.1°, occasional convulsive movements of the upper extremities. Fifth day involuntary discharges into bed, no iodine salts or albumen in urine. Great weakness and emaciation. Death on sixth day after the operation.

(39) Man, fifty-seven, tuberculous ostitis of ulna, resection. 150 to 200 grammes iodoform packed into wound. Lister. Second day large quantity of iodine salt in urine, frequent pulse, excited, restless, delirium at night suggestive of delirium tremens, gets out of bed. Third day strikingly quiet, lies for hours motionless, gives perverted answers to questions with stammering speech, urine and fæces passed into bed. Fourth day hard to rouse, small frequent pulse, neck muscles stiff. Seventh day unconscious, pulse and respiration more rapid, appearance of œdema of lungs, coma. Death on the ninth day. Slight chronic lepto-meningitis. Fatty degeneration of heart, kidneys and liver.

(40) Woman, sixty-three, periarticular abscess of left knee, incision, curetted. 100 to 150 grammes iodoform. Lister. Fourth day great headache, depression, loss of appetite, malaise, pulse quickened, temperature normal. Ninth day iodine reaction in urine. Eleventh day depression increased, constant somnolence, answers at random or not at all, urine involuntary. Twelfth and thirteenth day apathetic; difficult to rouse, lisps or stammers in answering, next day more comatose, stools and urine involuntary, temperature rising, symptoms continue to sixteenth day when there was œdema of the lungs. Death on sixteenth day. Heart muscles very flabby, spotted yellow and reddish brown, fatty degeneration of epithelium of cortex of kidneys.

(41) Woman, sixty one, double kolporrhaphia with perinæorrhaphia. Three to four grammes iodoform, strip of gauze. Third day (sixty hours) refuses food and medicine, fears poisoning, tries to get out of bed, delirium later, bites, scratches, cries out, hallucinations of sight, sleepless. Fifth day pupils narrow but react, thumbs turned in, neck stiff, mouth tightly closed, trismus exists, face strongly congested, eyes prominent and bright. Sixth day marked stiffness of neck, regular beating with the forearms, temperature 101°, pulse 80 full and strong, collapse in night, death. Death on the sixth day. Atrophy of one kidney, sclerosis of vessels of brain which presumably acted as predisposing conditions of poisoning.

(42) Boy, fourteen, chronic abscess in front of hip-joint, opened sinus. Washed out with ethereal solution of iodoform, iodoform and encalyptol bougies introduced every second day each containing five grammes. After a few days great depression, nausea, vomiting, pulse rapid and feeble 130 to 160, frontal headache, dull mental state, dull pain in epigastrium, emaciation, irregular pyrexia. Nine bougies used (about 5.0 grammes). Recovery in three weeks.

(43) Man, twenty-four, laryngeal phthisis. .06 grammes iodoform blown in daily. Thirtieth day irregular and intermittent pulse, fulness at stomach, faintness, exhaustion. Recovery immediate on leaving off iodoform.

(44) Woman, young, ecthymatous ulcerations. Scabs removed on head, surface sprinkled with iodoform powder. In a few hours scalp and neck swollen, quick pulse, nausea, restlessness. Recovery on seventh day.

(45) Woman, forty, syphilitic ulceration under chin. Ointment of one gramme iodoform to thirty, applied on lint. Ninth day face red and swollen, covered with vesicles. Twelfth day temperature 102°, delirious, weak and irregular pulse. Recovery on sixteenth day.

(46) Man, twenty-three, abscess under shoulder-blade. Iodoform 15.5 grammes applied in sinus in seven days. Seventh day delirious, temperature 104°, pulse 120, soon unconscious, stupor, pupils dilated, sphincters relaxed, sleepless, attempts to throw off bed-clothes, impaired muscular power, does not understand spoken words, symptoms lasted five days. Urine scanty, 1036 specific gravity, concentrated, no albumen or sugar, iodine reaction. Recovery on the eleventh day.

(47) Woman, forty, cancer of breast, secondary operation undermining skin. Twenty-five grammes iodoform powder strewn over wound and under flaps. Lister. Second day restless night, face very red, peculiar brightness in eye, pulse 110; next day very much excited, restless, cries out, spits all round herself, refuses food, constantly tries to pull off the bandages, appeared like one with acute mania, albumen and iodine in urine. The next few days unless under the influence of morphia, raved, tried to get out of bed, spat about, pulse 120 to 130, temperature 102°. Death on the ninth day.

(48) Woman, aged forty, ovariotomy (carcinoma). Partial removal. Twenty-five grammes iodoform powder put in the abdominal cavity. Lister. In one hour the temperature became 101.5°, patient became somnolent, feeble pulse, respiration very frequent and super-

ficial, sweating, sleepless night, vomited, very restless, thirst, pulse 140, respiration 32, pupils contracted. Next day same, iodine in urine. Death at night of third day with symptoms of dyspnœa.

(49) Man, forty-eight, sarcoma of thigh; amputation; drainage-tube. Drainage-tube rolled round in iodoform powder and placed. Renewed in two days. Second day, pulse 120, temperature normal; recognizes no one, does not know where he is; tries to tear off dressing, picks at bed-clothes, attempts to jump from bed. Symptoms last five days. Gradual recovery after the fifth day.

(50) Woman, fifty-eight, extirpation of rectum. A little iodoform rubbed into the cavity of the wound. Second day, restless at night; constantly talking, hallucinations; pulse rapid; end of week, loss of consciousness. Symptoms last three weeks. Recovery gradual after three weeks.

(51) Boy, of three; necrosis of tibia, operation. Wound filled with iodoform; dressing changed three times. After a time (day not stated) there was high fever, somnolence; on the skin of the body, flexor surfaces of both arms, and the inner surfaces of the thighs, a diffuse, bright red color, disappearing under pressure; islands of normal skin. Iodine, albumen, and epithelial casts in the urine. Recovery in three days. Renewal of treatment in a month brought on the same symptoms. The patient gradually became accustomed to iodoform, and was dismissed cured.

(52) Man, thirty-six, caries of rib; operation. Iodoform pencil in sinus every second day. On the tenth day, itching of the extremities; next day, urticaria nodules on the skin of the body and the extremities, from the size of a lentil to that of a three-cent piece, and of red color. Iodine in the urine; no albumen. Recovery.

(53) Woman, fifty, recurrent carcinoma of breast; operation. Thick layer of iodoform powder, nine inches long, reapplied after four days. On the tenth day, delirium at night, unconsciousness, patient emaciating, pulse weak, frequent, no fever, constant delirium, refuses food. Eleventh day, temperature 101.5°, collapse, death two days later. Death on the thirteenth day.

(54) Woman, of forty, collection of pus in knee-joint; incised, abscess in popliteal space and thigh, incision, drained. After two days, iodoform powder in wounds, and two pencils in sinuses (one gram. each). After a time (not stated), delirium, anxiety, idea of being followed, hallucinations, emaciation, feeble, rapid pulse, high fever for three days. Recovery in a few days.

(55) ——(?) Empyema necessitatis, incision. Lister. Pencil of two-grm. iodoform inserted twice. On seventh day, delirium, maniacal, pallor, anxiety; must be confined in a canvas jacket; temperature 101°, feeble pulse. Recovery in three or four days.

(56) Woman, of twenty-six, gummata on head and clavicles, ulceration, necrosis. Pills of iodoform 0.1 each (two to four daily), internally up to 42.0 grms. and unguentum iodoform, one part to ten, applied indefinitely. On the eighth day feels faint and weak on legs, double vision, lasting two and a half days, then vomiting, deep sleep, anorexia, lasting two days; then loud outcries, getting out of bed, confused talk, inability to seize and hold objects, double vision, headache. Symptoms improve, but last nine days. Recovery gradual after ninth day.

(57) Woman, sixty-nine, syphilitic necrosis of hard palate. Iodoform pills, 0.1 grm. each, two to four per diem (5.0 grammes had been taken in seven days). On the eighth day, somnolence, does not know what she says, walks clumsily and uncertain, like a drunken person; sleepless at night, headache, coma two days later, occasional incontinence of urine, which contains iodine, mild delirium, gets out of bed. Recovery gradual after the twelfth day.

(58) Woman, sixty-six, cancer of rectum; excision. Iodoform powder applied with finger to wound; iodoform gauze. In about thirty-six hours, cloudy sensorium, answers merely "yes" to all questions, difficult to feed, temperature normal, urine drawn by catheter, normal. In the night crying out; tries to get up. Next day, symptoms more intense; urine cloudy, contains enormous quantity of albumen, dark and transparent casts, epithelium, pus, fat drops. Later, iodine reaction in urine. Next day, restless, soporific, weak pulse (Pilocarpin injection, followed by much sweat and saliva; latter and urine contain iodine). Stiffness of extremities on attempting to flex them, extension easy; tracheal râles. Next day condition worse, pulse weak, intermittent, and irregular, cyanotic color, cold sweat. Transfusion, two hundred grams. blood, no reaction. Death on the fifth day. Autopsy reveals nothing.

(59) Woman, forty-seven, sarcoma of thigh; exarticulation. Iodoform gauze on third and seventh day, and on eighth day iodoform placed in wound. Gauze renewed thrice. On the sixteenth day, pupils dilated, pulse 164, passes fæces in bed, feels bad. End of day, jactitation, cries out, groans, speaks indistinctly, pulse very small, respiration very rapid; *transfusion of solution of common salt, 500 grams.;* pulse improves in strength; rate, as before, 160; continues very restless, and cries out terribly; early next morning have to apply canvas jacket; refuses food. Next day, fed by tube. Gradual improvement and recovery on fourth day.

(60) Man, forty-three, caries of rib; excision. Iodoform powder (amount not stated) to wound. Tenth to twelfth day, lassitude, anorexia, vomiting, diarrhœa; temperature normal, pulse rapid. Soon delirium, springing out of bed; tears off dressings, hallucinations, urine contains albumen and much iodine. Iodoform removed; delirium ceased, but patient remained lachrymose and rapidly emaciated. Death on —— day with dropsical symptoms.

(61) Woman, forty; lupus in face curetted. Iodoform powder (quantity not stated) to wound. In a few hours, vomiting, headache, nausea, iodoform smell and taste, diarrhœa, anorexia, lachrymosity, sensorium free, sleepless, rapid and striking loss of strength, pulse small and rapid, temperature 101° to 102°, urine contains iodine, removal of iodoform. Recovery in thirty-eight days. Recurrence of symptoms on renewal of treatment.

(62) Woman, twenty-four and a half, chronic uterine inflammation; six grams. iodoform (daily, .1 for sixty days) in the vagina. At length (day not given) depression, pulse 120, sopor. for three days; then excitation, gets out of bed, delirium, confusion, lasting some days. Recovery gradual.

(63) Man, twenty-one, suppurating glands in groin after urethritis; opened. Iodoform dressing for eight days. On the ninth day, temperature 102°; headache, somnolent, restless, dreams; omitted dressing; re-

covery. Renewed dressing, same symptoms. Recovery in few days.

(64) Man, fifty-eight, blow on head, wound five centimeters long. Wound filled with iodoform powder. On the tenth day, some fever, anorexia, headache, lasting several days; then confused, talking nonsense, attempts to escape; mania later. Quick pulse, iodine in urine. Iodoform omitted and bicarbonate of potash given internally. Recovery complete in seven days.

(65) Man, thirty-six, amputation of leg for diseased ankle. Lister. One week later, iodoform powder sprinkled on for four days, then syringed out with iodoform ether once. On the thirteenth day, breathlessness, anorexia. In the night, unconscious, by day absent-minded; tremor, temperature normal, pulse small, 120; strong iodine reaction in urine; next night escapes from bed; diminished consciousness. Recovery about the nineteenth day.

(66) Boy, of three, resection of hip; chiselling out acetabulum. Cavity washed out with saturated solution of iodoform in ether; then Lister dressing and sublimate gauze. Week later, again washed out and iodoform powder put in. In a few hours from the first application, vomiting, lasting fourteen days; great quantity of iodine in urine, little appetite. Hallucinations of sight by night, less frequent by day. Much emaciation; gradual improvement. Recovery from poisoning after a few weeks. Death from the disease some nine months later.

(67) Man, seventy-two, exarticulation for caries of toe-joint. Iodoform powder applied (small amount). On the eighth day, headache, melancholia; next day, excitation, getting out of bed. Recovery in eight or ten days.

(68) Man, old, crush of hand. Considerable iodoform powder, bound up with charpie. In a "few days," restlessness, confusion of thought, talks nonsense. Recovery shortly (not stated when).

(69) Woman, fifty-six, cancer of breast; extirpation. Iodoform powder (no statement of amount given). On the ninth day, "symptoms similar to meningitis," somnolence. Death on twentieth day. Fatty degeneration of heart, kidneys, liver; œdema of brain.

(70) Woman, fifty-two, cancer of breast; extirpation. Eight to ten grms. coarse crystalline iodoform inside, ten grms. outside. Dressing changed five times; Lister. Before the third day no appetite, refuses food. On third day, sopor, small pulse, moderate fever. Iodoform omitted ninth day; unconscious, cries out very much, excitement alternates with sopor; emaciation. Death on the thirteenth day. Œdema of pia, fatty degenerated liver, cloudy kidneys, granular heart muscle.

(71) Woman, thirty-seven, amputation of breast. Ten grms. iodoform, iodoform gauze. On the fourth day, delirium by night, weakness of memory by day, apathetic. Eighth day, excited, delirious, involuntary urine and fæces. Eleventh day, unconsciousness, thready pulse, exanthema of small, red spots on whole body, diarrhœa. Death on thirteenth day. Fatty degeneration of heart, liver, and kidneys.

(72) Woman, fifty-eight, amputation of breast. Ten grms. crystalline iodoform. Third night, restlessness, delirium, does not recognize attendants; symptoms continue and increase by day, gets out of bed. Sopor, thready pulse. Death on (?) day. Fatty degeneration of heart, kidneys, liver.

(73) Woman, forty, carcinoma of breast; parts of sternum and ribs removed. Twenty-five grms. powdered iodoform in wound. On the second day, after an unquiet night, acute mania in the morning, tears off bandages, escapes from bed, spits, cries out, refuses food; temperature 102°, pulse 120 to 130. Death on the ninth day.

(74) Woman, forty, carcinoma of ovary; partial removal. Twenty grms. crystalline iodoform to pedicle. Symptoms began on the first day with languor, somnolence, great restlessness, constant talking. Death on third day.

(75) Woman, forty-one, echinococcus of liver; opened. Fifteen grms. crystalline iodoform put in cavity. After twelve days, iodoform gauze. About the third week, great restlessness, dyspnœa, crazy ideas. Death in the fourth week.

(76) Woman, seventy, carcinoma of breast; amputation. Iodoform (amount not given) strewed on wound several days. After a few days, insane ideas. Rapid recovery after washing out iodoform.

(77) Woman, of fifty, carcinoma of breast; amputation. Iodoform (amount not stated) strewed into a place where secretion was retained a few days after operation. On the same day mania began, and lasted for eighteen days. Recovery after the eighteenth day.

Of these cases, the first thirty, as before stated, were reported by Koenig; also cases 49 and 50. Cases 31 to 34 are by Beck, 35 by Bermann, 36 and 37 by Czreny, 38 by Langsteiner, 39 and 40 by Henry, 41 by Schwarz, 42 by Clark, 43 by Coomes, 44 by Fifield, 45 by Goodell, 46 by Hayes, 47 and 48 by Hoeftmann, 51 and 52 by Zeissl; 53, 54, and 55, by Lingen; 56 and 57 by Oberlaender, 58 and 59 by Kocher, 60 and 61 by Pick, 62 by Seeligmüller, 63 by Schiffmann, 64 by Behring; 65, 66, 67, 68, by Kramer; 69, 70, 71, 72, by Hoepfl; 73, 74, 75, 76, 77, by Falkson.

(To be continued.)

A CASE OF STRICTURE OF THE ILIUM; LAPAROTOMY; STRICTURE INCISED, AND THE INCISION CLOSED WITH THE CŒCUM; DEATH ON THE NINTH DAY; AUTOPSY.

BY GEORGE W. GAY, M.D.,
Surgeon to the Boston City Hospital.

E. G., aged seven and a half years, had been troubled all his life with a most obstinate constipation. It was noticed soon after birth, and it had grown worse each year until at the time of the operation nothing had passed his bowels for thirteen days, although faithful and persevering effort had been made by means of cathartics and enemata to produce an action. About half of the patient's life had been spent in painful endeavors to empty the bowels. One or two days in every week were devoted to frequent dosings of cathartics aided by injections. A great deal of severe pain always accompanied these measures, besides occurring at frequent intervals between whiles. It was seldom that more than one or two days passed by without the patient's suffering more or less from the violent peristaltic action of the intestines. The abdomen was much distended, and the peristalsis was plainly visible, accompanied by loud gurgling, which apparently threatened an immediate dejection. The pain was principally referred to the right iliac region, and the peristalic movements were seen to begin there and to extend across the abdomen to the left side, and

[1] Read before the Surgical Section of the Suffolk District Medical Society, February 3, 1886.

return. There were two marked features in the case, namely, the absence of vomiting, and the fairly well nourished condition of the boy.

The patient was thoroughly examined under ether without detecting any obstruction, or abnormal condition to explain the obstinate constipation; strange to say that for a month after this etherization the bowels moved every day without aid. The constipation then returned, and soon became more intractable than ever, so that finally, medicine had no effect upon it. A second etherization failed to afford any relief, and it was soon evident that, unless the difficulty could be overcome by an operation, death would probably occur in the near future.

The absence of vomiting and of emaciation, the seat of the pain, and the origin of the exaggerated peristalsis, all pointed to the right iliac region as being the seat of the obstruction. After a careful consideration of the risks and future prospects in the case, the parents finally requested that an attempt should be made to relieve the patient.

The operation was performed November 24, 1885. Present and assisting Drs. Cheever, Post, Burrell, Kohr, and Timmins. Ether having been carefully given on account of the great distension of the abdomen, an incision, three or four inches in length, was made just above the symphysis on the median line. This was afterwards enlarged by a transverse cut extending toward the righ anterior spine of the ilium. A little ascitic fluid escaped from the cavity of the peritoneum, but there were no adhesions nor other signs of peritonitis.

The stricture was readily found located in the ilium at its junction with the colon. It was about an inch in length, and the calibre was half an inch in diameter, while that of the intestine above was four or five inches. The colon and rectum were full of hard fæcal matter, and the former together with the cæcum was very closely attached to the posterior wall of the abdomen, and the omentum in the vicinity of the stricture was considerably hypertrophied. The small intestines were distended with gas and semi-solid, well digested fæces.

The stricture was divided on that surface, which was free from omentum, by means of a longitudinal incision about two inches in length, extending from a point well above the constricted portion downwards into the cæcum. The bowel including the ilio-cæcal valve, was first laid open throughout this extent. Fæces were prevented from entering the peritoneal cavity by sponges packed about the wound in the bowel.

The large opening into the intestine was closed in the following manner: The ends of the incision were brought together, and the adjacent serous surfaces on each side of the wound were firmly secured in position by means of numerous interrupted, "iron-dyed" silk sutures, which did not include the mucous membrane. The wound having been closed throughout its whole extent in this manner the line of union was nearly transverse instead of being longitudinal as was the direction of the original incision. By this manœuvre the cæcum was brought up and set into the site of the stricture, not unlike a gusset, with the effect of giving a calibre of about one and a half inches to the constricted portion, a capacity nearly as great as that of the colon itself. It would seem as if ample room was thus afforded for the easy transmission of the intestinal contents into the colon, but as the autopsy showed, nothing ever passed this point after the operation.

Owing to the proverbial imperfections of the atomizer the operation was not carried out under full antiseptic precautions, but great pains were taken to keep up the body heat by means of flannels wrung out of hot carbolized water, and frequently applied to the abdomen, and the exposed intestines. The "toilet of the peritoneum" was made as carefully as after an ovariotomy, and the wound was closed by two separate and distinct sets of silk sutures, one for the peritoneum, the other for the skin, muscles and fasciæ. No drainage tube was inserted. Adhesive straps, iodoformed gauze, cotton wadding, and a flannel swathe completed the dressing.

The after treatment was most faithfully carried out by Dr. T. W. Kohr. The shock was not alarming, although the operation lasted over an hour. Very little vomiting followed. Morphiæ in doses of one-sixth of a grain was given subcutaneously every five or six hours, or as often as was required to control pain, and procure rest and quiet. The patient took food and stimulants fairly well till towards the last, yet he wasted very rapidly. Flatus escaped in the natural way on the second, as well as on several succeeding days, but no fæcal matter made its appearance. The urine, scanty at first, became more free, and was never suppressed. Two days after the operation there came symptoms of collapse; the pulse was 180, respiration sighing, skin pale and cool. Under a vigorous application of stimulants and external heat he rallied, so that on the fourth day the pulse was 112, respiration natural, and nervous system quiet. He took notice of his surroundings and called for his playthings. On the sixth day violent peristalsis set in again, and as nothing came from the bowels a careful trial was made with the catharties, which had formerly proved more or less efficacious, together with enemata of hot water, turpentine, castor oil, gruel and so on. An escape of a moderate amount of flatus was the only result. As the upper part of the abdomen was greatly distended, a No. 2 aspirator needle was introduced in three places giving exit to a considerable quantity of gas, thereby somewhat relieving pain, respiration and restlessness. On the eighth day this measure was repeated, but without relief to the enormously distended intestines. The symptoms were at this time most unpromising; pulse quick and weak, delirium, surface bluish, features pinched, and emaciation very marked. The question of opening the wound in the intestines, and allowing their contents to escape thereby, trusting to a future operation to close the sinus, had been carefully considered. In view of the facts that an artificial anus in the inguinal region gives no end of trouble in keeping the parts clean, and that it would in all probability be difficult, if not impossible, to ever close the fistula without reëstablishing the constriction, this procedure was not urged, and the parents decided, very properly as it seemed to me, not to have it done. Death from peritonitis and exhaustion took place on the ninth day after the operation.

The autopsy was made twelve hours after death. That portion of the wound situated at the junction of the two incisions in the abdominal walls had given way under the great distension on the last day of the patient's life. The rent was about two inches in extent, but there was no escape, nor even protrusion

of the intestines. There was a circumscribed peritonitis at the seat of the operation, limited to a space of four or five inches in diameter. The bowels were loosely glued together and to the abdominal walls over this area. There was no suppuration. The wound in the intestines was completely closed, although the union was not very firm. The line of incision was covered with lymph and a piece of omentum. Not a particle of fæcal matter had escaped into the peritoneal cavity. On opening the bowel above the seat of stricture, and passing in the fingers, the diameter of the intestine at that point was found to be fully an inch and a half, and yet none of the soft semi-liquid contents above had passed into the colon. The stricture had been relieved, and the normal calibre of the ileum had been restored, and yet the obstruction persisted after as before the operation. This fact was evidently due, not to constriction, but to a localized paralysis of the peristaltic action of the intestine. How much of this paralysis was due to the recent and limited effusion of lymph, and how much to the surgical lesions of the intestines, it is not easy to determine.

It is a well-established fact that adhesions sufficiently firm to interfere with peristalsis will produce as complete an obstruction of the bowels as will a contraction of their calibre. Fatal cases of strangulated hernia in which only a small portion of the intestine was involved, so little, in fact, that the capacity was very slightly diminished, have not infrequently been observed. However vigorous may be the peristaltic action, it seems to be powerless to drive the intestinal contents through a portion of paralyzed bowel, even of a very limited extent. This fact was well shown in a case of imperforate rectum lately under my care. Although the septum had been incised and was kept fully dilated with the finger, yet after a few days nothing came through, and the child died in two weeks with all the symptoms of obstruction: a distended belly, vomiting, and emaciation. At the autopsy, the rectum was found to be patent throughout, but greatly distended, and containing no fæces. It was evidently paralyzed by its lesions at the seat of obstruction. There was no peritonitis, nor other adhesions. The principal danger of a strangulated hernia is due to the arrest of peristaltic action, in other words, to the local paralysis of the vermicular action of the intestines.

In considering the case which forms the subject of this paper, the following questions may very properly be asked: first, why was not the constricted portion of the ilium cut out, and the remainder stitched to the colon? This point received due attention at the time of the operation, and was rejected for the following reasons: the parts involved were so vascular and so firmly fixed in position that the operation would have been much prolonged, much more severe, attended by very considerable hæmorrhage, and the shock and exhaustion would have been much more profound, which, in a child, is of great importance. It is very doubtful if the patient would have survived the operation. Besides no more space in the capacity of the bowel would have been obtained, nor would the intestines have been any more lax and movable upon their attachments. In short, it is not easy to see any advantages in this plan over the one adopted.

Second, why was not the colon dissected up, and freed from its attachments? Any one who will recall to mind the extensive surface by which the colon is held in its place, will readily understand the difficulties and dangers attending such an undertaking. And were this possible, the new adhesions, which must necessarily have taken place, would in all probability have been as troublesome as was the original condition.

The only other alternative, that of an artificial anus in the groin, had been disposed of before the operation was undertaken.

OPERATIONS FOR THE CURE OF INTESTINAL OBSTRUCTION.

BY HENRY O. MARCY, M.D.

Case I, 1881. Mrs. M., aged about sixty, a very stout woman of medium size. Had long been a sufferer from a large umbilical hernia, which, at times, gave great trouble and pain in reduction. When summoned, she had been three days in severe suffering, all means at reduction having failed. Vomiting, stercoraceous, and patient apparently in extremis.

Tumor nearly the size of the double fist. Skin tense and discolored. The thin sack was filled with necrosed omentum, in the centre of which was a loop of small intestine about three inches long, nearly black; it was slightly fissured on its mesenteric border. The omentum was sutured beyond the line of demarcation and cut away; the intestinal loop was returned with some misgiving as to the safety of its condition. The ring admitted the tips of two fingers only. The sack and ring were removed by an eliptical incision and closed, as after an ovariotomy. Cure ensued without complication, and patient is well to present time.

Case II, 1881. Mrs. C., aged fifty-six; under the care of Dr. White, of East Somerville. When summoned, found a large, fleshy woman, who had suffered for some days from intestinal obstruction, caused by an enormous umbilical hernia, size of fœtal head. The vomiting had been stercoraceous for thirty-six hours. The sac was sphacelated, and it was a question if operative measures were permissible. This having been determined, as the only hope, the contents of the sac, consisting of necrosed omentum and a long loop of small intestine, were exposed. The omentum was cut away, as in Case I, and seven inches of the small intestine, including a V-shaped piece of its mesentery attachment. The ends were carefully sutured with tendon used in the over-and-over stitch, care being taken, as far as possible, to include a double fold of only the peritoneal covering in each stitch. This was followed by a second row, just outside the first. Marked peristalsis supervened immediately on returning to the abdomen. The sac and ring were cut away by eliptical incision and closed, as before. Patient rallied slowly, and on the following day was comfortable. Death occurred in about sixty hours.

Autopsy showed the joined ends of the bowel encapsuled in an effusion of lymph, but no peritonitis. Death seemed incident to the prolonged suffering and exhaustion prior to operative, rather than surgical interference. Specimen, when shown to Cambridge Medical Improvement Society a little later, held water at point of juncture.

Case III, 1882. Mrs. B., colored, aged about forty. Had been well until within six months. Nursed her baby until within a few weeks. Had emaciated rapidly, and for some weeks vomited nearly all food taken.

[1] Read before the Surgical Section of the Suffolk District Medical Society, February 3, 1886.

Was seen by a number of physicians and her condition considered hopeless, as one of cancer.

When seen by me, the weakness was extreme, the emaciation marked, and through the thin abdominal wall could be easily felt a small, movable tumor. This was believed to be the thickened pylorus, and since movable, it was determined to advise exploration. Assisted by Drs. Holt and Nelson, of Cambridge, I found the stomach nearly empty; the pylorus, enlarged in a firm, hard, movable mass, size of large walnut, was without abnormal adhesion or surrounding glandular infiltration. It was determined to resect. Tied above and below with rubber ligature, packed about with sponges, for the better protection, and excised the mass with scissors. The duodenum was, by nearly half, too small to fit into the stomacic section, which was reduced to size by a V-resection of the lower border. The parts were joined as in previous cases, and the only complication was a sharp hæmorrhage from a branch of the gastro-duodenalis artery of considerable size, in the superior border of the wound. This was quickly secured, the peritoneum cleansed, and the wound closed. The patient rallied slowly, but well; was nourished by rectal enema, and the second day was bright and comfortable, gave direction as to household affairs, and was very hopeful. She sank at the end of about seventy hours from exhaustion. The autopsy showed a limited effusion of lymph; no peritonitis. The wound was well closed, and there had been no escape of the contents of the stomach into the abdomen. The other organs were healthy.

CASE IV, 1885. Mrs. B., aged about sixty. In previous good health, had all the symptoms of a sudden intestinal obstruction. When operation was made, had not had a free dejection for three weeks, and for some days, stercoraceous vomiting. The case was one of Dr. Cunningham's, of Cambridge, and it was believed that the cause might be found in some mechanical obstruction, as band or twist, since it ensued suddenly, and had persisted as complete. Aided by Drs. Cunningham and Somers, of Cambridge, I made a careful exploration. The abdomen was greatly distended, and the intestines gave much trouble in keeping within control. Used the aspirator, but failed to reduce distension of intestines, as the needles soon filled with the thin, churned-up contents. After a little examination, detected constriction near illeo-cæcal junction in a nodule of cancerous mass, size of end of finger. This easily broke under manipulation, and left nothing less than resection as the alternative. Tied with rubber ligature, and cut out the piece with scissors. The distension was so great, that it was thought wise to empty the bowel of a part of contents. Two quarts or more of liquid fæces were allowed to escape into a bowl outside the abdomen, the cavity having been protected by sponges.

The ends of the bowel were then joined as in previous cases, and the wound closed. The patient did not fully rally, and died about twelve hours after from shock. No autopsy. The operations were all conducted under thorough antiseptic precautions.

— At the Paris Société de Thérapeutique, Dr. Bouloumié lately exhibited a biliary calculus weighing 20 grammes = 5.144 drachms. It was of cylindroid shape, and measured 2 inches in length, 3¼ inches in circumference, and on section, 2 inches in its long axis.

CLOSURE OF ARTIFICIAL ANUS BY INTESTINAL SUTURE.[1]

IN THE SERVICE OF DR. C. B. PORTER.
REPORTED BY DR. W. M. CONANT.

MR. S., a carpenter, entered the Massachusetts General Hospital on the 4th of June, 1884, with an artificial anus on the right side of the abdomen.

The history is as follows:

He had had for eight years a right inguinal hernia which from time to time he had been in the habit of reducing himself, without any difficulty, until about two years ago when the hernia came down and he discovered that he could not reduce it. After trying some time without success he became alarmed and sent for a physician.

The physician, after many trials, failed to reduce the hernia by taxis and the man was put to bed. The man was kept in bed for nine days, and then was allowed to get up and have a movement and afterwards sit up for five hours. At that time he says he had a feeling as if something had broken in the region of the hernia. For several days after he was allowed to get up and use the cabinet chair whenever he wished to have a movement of the bowels. He used the chair for five days, and on the fifth day there was a rupture of the skin on the right side; and ever since there has been an opening through which his fæces pass.

He had great difficulty in keeping himself clean, and for the last eighteen months he had been confined to his room and to his bed. So great a burden had he become to himself and family that he had decided to have an operation performed even if it should prove unsuccessful.

Examination. Patient was about fifty. Frame much emaciated, but general condition was fair.

On the right side of the abdomen there was a circumscribed portion, as large as a man's palm, that was very red and much excoriated. There were three distinct openings in the skin, and the skin about them was very indurated. From these openings the fæces oozed with every breath, and on every slight impulse of any kind, as a cough or attempt to change position.

The three openings were situated somewhat as follows: —

No. 1 was just above the middle of Poupart's ligament.

No. 2 was about an inch higher up and a little to the outside.

No. 3 was about three inches higher and was four inches from the middle line of the body.

There was also a large mass of tissue in the right side of the scrotum; and the entire right side of the scrotum was enlarged and somewhat tender to the touch.

The man was put to bed: the openings were washed several times a day with carbolic acid 1–80; oakum pads were applied to catch the fæces. For a week every endeavor was made to build up the man's general condition.

On June 12th, eight days after he entered the hospital, the man was operated on.

Patient having been etherized, Dr. Porter made an incision in the line of the inguinal canal down upon the abdominal rings. This incision was about six

[1] Read before the Surgical Section of the Suffolk District Medical Society, May 6th, 1885.

inches long and began above opening No. 2 and extended through No. 1 into top of scrotum. Later this incision was extended to No. 3 and it was then found that only No. 2 opened into the abdominal cavity. After careful dissection the two ends of intestines were discovered protruding through the ring and glued to the sides of opening No. 2. These ends proved to be only the anterior portion of the intestinal wall, as, on drawing out the intestines, the posterior portion was found to be intact. The intestinal edges were freed; a portion of the intestines lifted out and placed on towels rung out in hot carbolic 1-100. The edges of the ruptured portion were refreshed and then carefully approximated and sewed with split-silk sutures. Sutures were placed very near together, not being more than a sixteenth of an inch apart.

Then the mass in the scrotum was examined and found to consist of omental tissue which had become adherent to the scrotal tissue. A portion of this mass was cut off and then was allowed to remain with the hope that it might be nourished by the surrounding tissue and so cause less disturbance than if time were taken in removing it.

After the intestines were sewed up the hernia was replaced through the ring and the ring was then stitched up.

A drainage tube was placed in most dependent part of the wound and then the wound was sewed up. A Lister dressing was applied, as during the operation full Lister precautions had been used.

Patient was taken to the ward and heaters were put about him. He came out of his ether nicely having but very little vomiting. Was given nothing but ice until evening, when he was allowed to drink a little strong French coffee, which relieved him of his ether sickness.

June 13th. Patient passed a very comfortable night and obtained considerable sleep. Had small amount of nourishment during the day, but only in liquid form consisting largely of beef tea.

June 14th. Lister changed this morning, wound in excellent condition. No sign of redness or soreness. Patient in the best of spirits and very sanguine that the operation will prove a success. This afternoon, next day after the operation, the patient passed wind.

June 15th. Lister changed. Everything looked favorable. Had movement of bowels, second day after operation.

June 16th. Lister changed. Wound has a red and angry look, but there is no temperature to indicate formation of pus.

June 17th. Lister changed. An abscess was discovered leading into the scrotum, and on being opened several ounces of foul smelling pus flowed out. This was on the fifth day after the operation. This abscess is due without doubt to the omental tissue left in the scrotum and is the cause of the increase in temperature.

June 18th, 19th. Lister changed. Abscess discharging freely. Rest of the wound healed by first intention and all stitches have been removed. Patient allowed a more nutritious diet, as boiled eggs, rare steak or chop, a little toasted bread, and an occasional egg-nog.

June 21st. Lister changed. A mass of dark, foul-smelling tissue pulled out of the scrotal abscess. This was on the ninth day after the operation.

June 22d. Lister changed. Another mass of tissue like that of yesterday withdrawn from scrotum.

June 23d. Lister omitted. Very little discharge from scrotum. Patient placed on extra diet.

July 1st. Allowed to get up and sit in a chair. This was on the nineteenth day after the operation.

July 4th. Allowed to use a wheel-chair alone.

July 8th. Patient very anxious to go home, therefore on the twenty-sixth day after the operation the man was discharged.

REPORT ON MEDICAL CHEMISTRY.

BY WILLIAM B. HILLS, M.D.

CARBONIC OXIDE.

Zaleski,[1] as a result of experiments on cats with carbonic oxide, comes to the conclusion that when the gas is injected into the peritoneal cavity it acts poisonously, though not rapidly; that it is absorbed by the blood, though more slowly than from the lungs; that it appears unaltered in great part, if not entirely, in the expired air; that it is not detectable in the expired air, if, instead of the gas itself, carbonic oxide blood has been injected. Zaleski's results are contrary to those of Kreis, who found no carbonic oxide in the expired air after the gas had been injected into the peritoneal cavity, or subcutaneously. Zaleski's experiments have an important bearing on the elimination of the gas in ordinary cases of poisoning by it, since it is disputed by many that the gas is excreted unoxidized. These allege that the unoxidized gas actually found in the pulmonary air is merely a portion of that which has never been absorbed by the lungs in ordinary inhalation experiments.

N. Grehant[2] declares, in opposition to Kreis, that in poisoning by carbonic oxide, the gas is not in any degree oxidized in the system to carbon dioxide, but is wholly eliminated unaltered.

ATROPINE.

Kratter[3] contributes a long paper on poisoning by atropine, based on a study of eight cases in his own experience. The following are his conclusions: —

(1) The detection of atropine in the body is certain, provided proper methods of analysis are employed.

(2) The urine is especially valuable for this purpose, since atropine is quickly absorbed and entirely excreted through the kidneys, apparently without undergoing change. It can be detected in the urine in cases which have not terminated fatally.

(3) The examination of the pure crystalline residue in polarized light, though not conclusive, is to be recommended, since the crystals of the sulphate are sufficiently characteristic to render the detection of atropine in this way tolerably sure.

(4) Positive proof of the presence of atropine is only to be found in its physiological action. The human eye is best of all for this purpose, since it is the most sensitive. The eye of the cat is also very sensitive.

(5) Atropine shows great resistance to putrefactive processes, and can be detected in bodies which have been buried for some months.

(6) Owing to the rapid elimination of atropine through the kidneys, the results of the chemical

[1] The London Medical Record, March 15, 1886, page 121, from Archiv. fur Exper. Pathologie und Pharmacie, xx., page 34.
[2] Comptes Rendus, 1886, page 825.
[3] Vierteljahrsschrift fur Gerichtliche Medicin, XLIV, page 52.

analysis are liable to be negative if the patient survive for some days.

Professor Flückiger[4] confirms the observation made by Mr. A. W. Gerrard in 1884, and noticed at that time in these "Reports," that the mydriatic alkaloids are possessed of quite exceptional alkaline power towards mercuric chloride, from the aqueous solution of which they precipitate mercuric oxide, the other natural alkaloids giving no precipitate at all with mercuric chloride, or, at least, in no case separating mercuric oxide.

Flückiger now makes the further observation that atropine, quite exceptionally, is able to impart a red coloration to phenolphtaleïn paper, thus contradicting the assertion made by him in 1884, that alkaloids generally were deprived of such an action. He has demonstrated that atropine is the only alkaloid (speaking, however, of the more generally used alkaloids) which displays the same action as the inorganic alkalies. This is a remarkable coincidence, and goes far to favor the suggestion that atropine must be peculiarly constituted, differing from other solid alkaloids, none of which, as far as we actually know, show the same behavior towards mercuric chloride and phenolphtaleïn. The author has also tried other coloring matters, and found them to be acted upon by atropine in the same way as by potash and soda. Atropine, therefore, has an alkaline power like the hydrates of sodium and potassium, differing in this respect from (probably all) other alkaloids. The author states, however, that mercurous chloride is not blackened by atropine as it is by the alkaline hydrates. Mr. Gerrard,[5] on the other hand, asserts that this statement is contrary to fact, and he has placed on record the experiments on which his assertion is based.

Flückiger describes modifications of the other tests for atropine. The original paper is referred to for details. It is to be borne in mind that phenolphtaleïn can be used in the identification of atropine only in the absence of the inorganic alkalies.

THE PHYSIOLOGICAL ACTION OF CERTAIN COLORING MATTERS.

P. Cazeneuve and R. Lépine[6] state that rosaniline sulphate is entirely without physiological action, even in quantities of several grammes, whether taken into the stomach or injected into the veins. Safranine, however, when injected into the veins of a dog, caused rapid acceleration and weakening of the heart's action, severe diarrhœa, and often albuminuria, ending in death. If administered through the stomach, diarrhœa was the only serious result, the irritant action of the poison probably preventing its absorption.

The authors[7] have also made experiments with three coal-tar yellows, which are used somewhat largely for coloring confectionery and beverages: namely, *Manchester*, or *Martius yellow* (dinitronaphthol yellow); *NS yellow*, a sulphonic derivative of the first color; and *solid yellow*, a sulphonic derivative of amidoazo-orthotoluene. These were administered through the alimentary canal, or were injected into the veins. Manchester yellow, even in small doses, has a somewhat poisonous action, and produces vomiting, diarrhœa, panting respiration, and a high temperature, followed by death. NS yellow has no appreciable toxic action, and solid yellow is at least as innocuous.

PHYSIOLOGICAL ACTION OF ACETOPHENONE.

Mairet and Combemale[8] have made experiments on dogs, cats, rabbits, guinea-pigs, and sane and insane human beings, the acetophenone being administered in several different ways. This substance is not a hypnotic, and its advantages as a sedative are very doubtful. It acts on the nervous system, and also produces congestive and inflammatory lesions of the kidneys, lungs, and liver.

QUANTITATIVE ESTIMATION OF ARSENIC BY THE BERZELINS–MARSH METHOD.

According to W. P. Headden and B. Sadler,[9] this method gives satisfactory results under the following conditions: The zinc must be free from carbon and pure in other respects. The arsenic must be present in the form of arsenious acid. Iron, copper, platinum or their salts, and probably the other heavy metals and their salts must be absent. The calcium chloride used for drying the gas must be neutral, and must not be used more than once. The action must be slow and regular, and the decomposition tube kept at a dull red heat. Two decomposition tubes are necessary, about three per cent. of the arsenic being deposited in the second tube.

COPPER.

Du Moulin[10] has recently studied the action of copper compounds and finds that copper sulphate may be administered to dogs and rabbits in doses of three, four and five grammes, without producing any other symptom than vomiting. Doses of one-half to one gramme of copper sub-acetate were administered daily for six weeks to dogs and rabbits without producing poisonous effects. Vomiting occurred at first, but ceased after four or five days and did not recur. Oxide and carbonate of copper were administered to rabbits during a year without causing any trouble. Compounds of copper with fatty acids gave similar results. The author has administered copper sulphate to infants in doses of twelve to fifteen centigrams without producing any symptoms of poisoning.

BORIC ACID AND BORAX.

Dr. Johnson[11] has made a number of interesting experiments relative to the elimination of boric acid and borax. The amount of boric acid administered varied between 0.90 gramme and 3.6 grammes daily; that of borax was 1.5 grammes. In one case, in which the dose was 3.6 grammes, symptoms of poisoning ensued. In the remaining experiments the only noticeable effect was occasionally an increased diuresis. The compounds of boric acid appear very quickly in the urine after their internal administration; in one case, in ten minutes after administration by the mouth. They could ordinarily be detected in the urine for eight days after the last administration; in one case for fifteen days. The acid was frequently detected in the perspiration, in one case for two days after the

last administration. The saliva gave a feeble reaction in three cases. There was great irregularity as regards the fæces. The acid appeared quickly in the urine after its application to the skin in the form of an ointment, and the reaction was obtained for two or three days after the last administration.

BISMUTH.

Steinfeld [12] contributes a long paper on the toxic effects of the salts of bismuth. The bismuth was administered in the form of soluble double citrate of bismuth and sodium, and was in every case injected into the circulation or subcutaneously. Bismuth is fairly rapidly excreted, especially through the kidneys so that after ten to fifteen hours it is not possible to detect the metal in the urine or blood though it is still present in the intestines, through which (mainly the large intestine) it is also excreted. It is not excreted by the liver or pancreas.

TIN.

Dr. Patenko,[13] of St. Petersburg contributes a paper on the toxic and physiological effects of metallic tin and the bichloride of tin. His conclusions, which are based upon twenty-one experiments on frogs, dogs and guinea-pigs, carried on in the laboratory of Prof. Vulpian, are as follows:

(1) Metallic tin has no appreciable action on the system.

(2) The bichloride of tin injected subcutaneously in small amounts produces a local anæsthesia. The salt may be wholly absorbed without producing any lesion, or may give rise to the formation of small abscesses. When larger quantities (0.100 gramme) are introduced, gangrene results at the point of injection. This tends to spread and may involve not only the skin but the subjacent organs. These effects are due solely to the caustic action of the salt.

(3) The bichloride injected into the peritoneal cavity provokes a peritonitis, which is usually circumscribed if the amount injected is small, but invariably general if the amount is large.

(4) The bichloride introduced into the bloodvessels of a dog, in doses of 0.015–0.020 gramme, produces no bad results. It is rapidly fatal in doses of 0.050 gramme. The toxic dose for a dog weighing seven kilogrammes appears to be between twenty and fifty milligrammes. After death, the membranes of the brain are found injected; the tissue of the brain moderately hyperæmic; the sinuses filled with dark liquid blood; lungs normal; left ventricle contracted, but yet containing a small amount of dark liquid blood; right ventricle dilated; liver and kidneys congested.

(5) The bichloride introduced into the stomach of a dog in doses of 0.5 gramme produces no symptom of poisoning, although it coagulates the albuminoid matters and mucus with which it comes in contact. One gramme administered daily for more than two months produced no other effect than vomiting, which occurred first on the fifth day. The vomiting occurred soon after the introduction of the tin compound, but did not continue long. The general health of the animal remained unimpaired throughout the whole experiment.

[12] The London Medical Record, March 15, 1886, page 121, from Archiv. für exp. Path. und Pharmacie, xx, page 40.
[13] Archives de Physiologie, 1886, page 33.

VOLATILE FATTY ACIDS IN URINE.

R. v. Jaksch [14] finds traces of fatty acids in normal human urine; the amount does not exceed 0.008 grammes per diem. By oxidizing normal urine, formic, acetic, and probably butyric acids are formed to the extent of 0.9 to 1.5 grammes in the daily quantity. Under certain pathological conditions, the proportion of free acid is increased, but not that obtained by oxidation. In cases of fever and liver disease, from 0.6 to 1 gramme of free acid, chiefly acetic, was found.

THE FORMATION OF HIPPURIC ACID.

H. Tappeiner [15] has made investigations the result of which shows the presence in the alimentary canal of phenyl-propionic acid (one of the putrefaction products of albumen) and increases the probability of Salkowski's suggestion, that hippuric acid in the urine may be derived in part from putrefactive changes in the alimentary canal.

PEPTONURIA.

H. Paconowski,[16] has examined the urine for peptones by Hofmeister's method in 211 cases of different diseases, with positive results in 94 cases. He divides the latter into cases of acute and chronic peptonuria. He corroborates the statements of Maixner and von Jaksch relative to the influence of suppurative processes on acute peptonuria. Earlier observers disagree with reference to peptonuria in case of ileotyphus. Maixner found peptones in the urine in this disease while von Jaksch obtained negative results in eighteen cases. The author investigated 36 cases and found peptones in 25, but only at the beginning of the period of defervescence, so that the peptonuria was indicative of beginning improvement. The result was similar in other acute infectious diseases. The author's explanation of the appearance of peptones assumes that the products of typhus processes in the intestines and mesenteric glands are reabsorbed with the occurrence of healing, while during the period of ulceration they are quickly separated from the body with the stools. The author determined the presence of chronic peptonuria in tuberculosis of the lungs. He examined the urine in twenty-five cases of this disease and found peptones in eleven, and in most of these only in the early stages of the disease when the physical signs were scarcely perceptible. The author thinks that as the destruction of the lung tissue proceeds, the vessels become less and less capable of absorbing the peptones which have their origin in the broken-down products.

The author also investigated thirteen cases of carcinoma of various organs and found peptones in the urine in ten.

— The address in Medicine at the forthcoming meeting of the British Medical Association will be delivered by Dr. John S. Billings of the United States Army.

— The English hydrophobia commission is said to be retarded in its investigations by the difficulty of obtaining a rabid dog with which to test the efficacy of the protection afforded by inoculation.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SURGICAL SECTION.

S. J. MIXTER, M.D., SECRETARY.

FEBRUARY 3d, 1886. The chairman, DR. GEORGE W. GAY, presiding.

DR. D. W. CHEEVER reported

A CASE OF CHRONIC OBSTRUCTION FROM CONGENITAL MALFORMATION OF THE BOWELS; TENTATIVE OPERATION; DEATH.

The child upon whom the operation was performed, was a patient of the Drs. Webber, in Cambridge, with whom he was twice seen in consultation. At birth, nothing unusual was noticed, but three or four days after, symptoms of obstruction became very marked. These symptoms were finally overcome by the use of cathartics. Recurrent attacks of a similar nature were treated in the same manner. The patient was first seen by the reader when four months old. On examination under ether the rectum and anus appeared to be perfectly normal, and no tumor of abdomen could be felt. The stools were of usual size, showing that the point of obstruction was above the sigmoid flexure. The parents at this time refused any operative interference.

After a year and a half, the patient being then nearly two years old, he was seen again. The rectum and anus were again found to be normal but the abdomen was much enlarged, the child presenting a peculiar conical appearance, the head forming the apex and the abdomen the base of the cone. He was fairly well nourished but every little while had attacks of obstruction, accompanied with vomiting and pain. An operation for the formation of an artificial anus was proposed, but refused by the parents, who, however, were willing to accept any other operative procedure and the following operation was performed under ether and with antiseptic spray. A median incision extending from the pubis to the umbilicus, exposed a large, flat, ovoid sac, occupying the lower part of the abdomen. The incision was enlarged and the tumor was lifted out. It was found to consist of a dilatation of the intestine containing about two quarts of fæcal fluid, and at one end was attached to a piece of contracted and strictured intestine, twelve to eighteen inches in length, ending at the sigmoid flexure. This was quite impervious to solid fæces.

The dilated and constricted intestine occupied such a large portion of the large intestine that excision with union of the divided ends was impossible, and an artificial anus being ruled out by the express wish of the parents, the only thing that could be done was to aspirate the sac, return it to the abdomen and sew up the incision. This was accordingly done, peritoneal surfaces being approximated, and the boy recovering well from the ether, did perfectly well for six days, when severe symptoms of obstruction presented themselves, accompanied by great swelling of the abdomen, the abdominal wound being forced apart, and death followed in thirty-six hours.

The important and peculiar points in this case are the presence of such a length of strictured intestine, undoubtedly congenital, and the size of the tumor formed by the dilated intestine above the stricture. The reader had never before seen a case where the abdominal wound, apparently healing by first intention, had been forced open by intestinal distension.

DR. C. B. PORTER exhibited a patient upon whom he had performed an operation for the closure of an artificial anus following sloughing hernia. The case was reported by Dr. W. M. Conant [1] before the Surgical Section, May 6th, 1885.

DR. PORTER said that in this case the pillars of the ring were united with catgut and a radical cure of the hernia obtained. This was the second successful case that he had had. In a third case where a fæcal fistula had resulted from a crush of the abdomen by a cart wheel, it was found impossible to lift out the intestine on account of adhesions, and the patient had died eighteen hours after the operation.

DR. H. I. BOWDITCH recalled to mind many cases in his past practice, where the lives of the patients might have been saved or made endurable by the methods of modern intestinal surgery. Cases of non-malignant stricture of the intestinal tract, obstruction by gall stones, and many other diseases of the abdominal organs, should no longer be regarded as incurable.

DR. GEORGE W. GAY reported a case of

STRICTURE OF THE ILIUM; LAPAROTOMY; DEATH ON THE NINTH DAY; AUTOPSY.[2]

DR. CHEEVER emphasized the fact that in cases of chronic obstruction, the intestine above the constriction becomes much dilated and its muscular coats paralyzed, thereby greatly increasing the difficulty of operating and the danger of a fatal result.

DR. PORTER said that the case reported by Dr. Gay interested him particularly, as in his first case the portion of intestine excised had been at the ileo-cæcal valva, the site of the stricture in the case reported by Dr. Gay.

DR. HENRY O. MARCY reported four cases operated on by him for

INTESTINAL OBSTRUCTION.[3]

DR. MARCY exhibited frozen sections through the tumor of the pylorus, (CASE III) mounted in balsam as stereopticon slides. These showed the complete occlusion of the canal. He expressed his belief that had the operation been performed earlier, the outcome, very probably, would have been different, since the case was a very favorable one for operation. Dr. Marcy strongly advocated the use of the tendon suture, prepared after Mr. Lister's formula, from the tail of the Kangaroo in the over and over stitch. It is reliable, non-irritating, holds the enclosed parts more firmly and evenly, and has the great advantage of saving time in the rapidity of application, while it requires but a single knot in the entire circuit of the bowel. The second row may not be necessary, but it gives a further protection, and requires but a very few minutes in its application.

DR. J. W. CHADWICK reported a case of

INTESTINAL RESECTION FOR MALIGNANT STRICTURE OF THE LARGE INTESTINE.

In this case there had been symptoms of obstruction for six months, and the slight hæmorrhage for three months. The right side of the abdomen was some-

[1] See page 80 of this Journal.
[2] See page 77 of this number of the Journal.
[3] See page 79 of this Journal.

what fuller than the left. An incision was made to the right of the rectus, and a prolonged search was necessary before the obstruction was found. It was at last discovered in the large intestine about three inches above the ilio-cæcal valve, well up under the liver. The constricted portion, about three inches in length, was excised, and the dilated upper end united to the lower contracted one. Great difficulty was experienced in introducing the stitches according to the rule of Lembert, as the dilated portion was very thin, and in both ends the coats of the intestine were very movable one on the other. Death from shock took place in twelve hours.

Time seems to enter as a very important factor in these operations, and familiarity with the methods of operating will probably bring the best results.

THE AMERICAN OTOLOGICAL SOCIETY.

The nineteenth annual meeting of the American Otological Society was held at the Pequot House, New London, Connecticut, July 20, 1886.

The Society was called to order by the President, Dr. J. S. Prout, of Brooklyn.

A business committee consisting of Drs. Webster, Holt and St. John was appointed.

Dr. Friedenburg and Dr. Bartolett were invited to take part in the proceedings of the society.

The treasurer then made his report stating that there was a balance of $51.82 in the treasury.

Dr. S. Sexton, of New York, read the first paper, entitled

ACUTE AND CHRONIC PURULENT INFLAMMATION OF THE MIDDLE EAR TRACT AND THEIR COMPLICATIONS.

The paper was based on a study of over two thousand cases of acute purulent inflammation of the middle ear, acute catarrhal inflammation of the middle ear, and chronic purulent inflammation. Acute catarrhal inflammation was included in the consideration of acute purulent inflammation, since in the beginning, the conditions were probably the same although not always going on to suppuration. Of this number there were twelve deaths.

The speaker held that in no disease of man is a knowledge of regional anatomy more important than in diseases of the middle ear and gave a *résumé* of the anatomy of the temporal bone, accepting the description of Professor Leidy as the most satisfactory.

The temporal bone at birth is peculiar in the fact that the tympanum and mastoid antrum are about as large as they ever become in adult life. The petroso-squamosal suture is imperfectly closed.

The symptoms were next referred to. Brain symptoms such as headache, vertigo, pain, delirium, nausea and vomiting may occur in consequence of middle ear disease without lesion of the cerebral structure.

The prognosis of purulent inflammation of the middle ear is favorable when non-meddlesome treatment is adopted, both as regards life and the preservation of hearing. Out of twenty thousand cases of ear disease, where the patient has been seen at the beginning of the attack, no fatal case has occurred. Cases which have come under observation after severe symptoms have appeared, have given twelve deaths. Some of the fatal cases occurred long after the ear trouble had abated.

In regard to treatment, the speaker recommended incision of the drum head. Trephining of the mastoid process has been recommended by some authorities. Dr. Sexton took up a consideration of the indications which have been regarded as calling for the application of the trephine and held that they were insufficient. From his experience, he was led to believe that drainage could be best maintained through the natural channel.

The speaker also described

A NEW OPERATION FOR THE RADICAL CURE OF CHRONIC PURULENT INFLAMMATION OF THE MIDDLE EAR TRACT.

Since describing a form of chronic purulent inflammation of the attic in a paper read before the society last year, it had occurred to him that something might be done with these cases by means of an operation. It seems especially desirable to cure these cases, when the ear remains simply a reservoir for purulent matter, liable at all times to infect the system. It is found that in the greater number of these cases that the remaining portion of the conducting mechanism no longer serves to aid in the transmission of sound but acts rather as an obstruction to drainage. Where the membrana flaccida and a portion of the ossicular chain only remain, the former often becomes thickened and everted, forming with the altered mucous membrane a pouch for the retention of putrescent matters which may slowly escape. Where granulation tissue or polypoid growths are present in the attic or antrum the escape of secretions is still further interfered with. This produces long continued and great irritation.

The author had observed that in a number of cases where the transmitting mechanism had been lost, a spontaneous cure followed, and it occurred to him that the curative action of nature might be imitated with advantage. Where drainage from the attic and antrum is interrupted, a cure can only be assured by an operation permanently clearing the passage outward from the tympanum.

Last year the operation was tried on a long-standing case of otorrhœa, due to chronic purulent inflammation of the attic. In order to avoid the danger of using an ordinary lamp in connection with the administration of ether, an electric light was used. The operation has since then been fully performed in several cases.

The first step of the procedure is to separate the membrana flaccida from the edge of the auditory plate and to remove any portion of the membrana vibrans adherent to the auditory ring. If the malleus and incus remain in situ, it is well to divide the tendon of the tensor tympani muscle when present, where it leaves the handle just behind the short process and below the chorda tympani. The chorda tympani when remaining is then divided where it enters the tympanum at the pyramid and also at its exit into the canal of Hugier. The long process of the malleus, being also received into the glenoid fissure by means of this short oblique canal, along the chorda, may be more or less detached at the same time. The detached tissues and ossicles should now be removed with the forceps. It will frequently be found that the incus having been displaced, still remains. It may be removed with the attic scraper, which is to be introduced from below

and passed up along the inner wall of the tympanum, when the distal extremity may be carried over the incus or malleus, if the latter bone remains, and by traction the ossicles can be detached; polypoid masses, granulation tissue and the products of inflammation may now be removed with the cutting curette or cutting forceps, and the parts dressed with a four per cent. solution of cocaine to relieve pain.

There is usually free bleeding during the operation, often sufficient to protract it and increase its difficulties.

The effect of injury or destruction of the chorda tympani nearly always manifests itself in some way, but had never in his experience been a matter of serious import. Disturbances of taste sometimes follow the operation, but they gradually disappear and leave the sense of taste unaffected.

The drum should be kept well cleansed and light dressings of boracic acid applied until healing takes place. The salicylic acid powder may be applied as freely as can be borne. In some cases this is irritating at first, but tolerance is soon established. It may then be kept up until the parts cease to discharge.

In the cure resulting from this treatment, a dermic transformation of the tympanum takes place, but mucus may occasionally gain admission from the Eustachian tube during recurrent head catarrh or on blowing the nose. This should be frequently removed with cotton wool, and if necessary the drying applications renewed for a time.

Where the incuso-stapedial connection remains, I should not hesitate to perform this operation, unless a very considerable portion of the membrana vibrans was present.

The instruments employed and some of the diseased ossicles removed, were exhibited.

DISCUSSION.

DR. C. R. AGNEW, of New York. I infer from the speaker's remarks that he objects to the opening of the mastoid.

DR. S. SEXTON, of New York. I have never had any difficulty in obtaining drainage in cases of periostitis externa by a free incision with a small tenotomy knife.

DR. AGNEW. Where the inflammation has come to involve the mastoid cells, I think that some portion of the external wall of the mastoid should be removed. The objection to the trephine is that it does not expose a sufficient area of the cancellated tissue of the mastoid. I do not see how the new operation, which has been described, will be of service in these cases.

DR. SEXTON. The new operation I recommended only in chronic cases.

DR. H. KNAPP, of New York. The upper tympanic pneumatic cells resemble, to a certain degree, the frontal sinuses. These have a direct natural drainage through the infundibulum into the nose. When this is closed by disease, the lateral part of the sinus over the orbit dilates, and the cavity is more easily reached and more effective drainage is obtained by opening the sinus from the orbit. In a like manner, we obtain, in most cases, easier and more effective drainage of the supra-tympanic cells by opening the mastoid cells with which they communicate.

PAINLESS, AND ONLY SLIGHTLY PAINFUL ULCERATION OF THE MEMBRANA TYMPANI, PROBABLY OF A TUBERCULAR NATURE,

by DR. A. H. BUCK, of New York.

The speaker stated that the recognition of the early stages of tubercular disease was important, and the object of the paper was to call attention to the features by which this could be recognized. Three cases had been seen by the author. The patients were in a condition of fair general health; one of them had suffered with back-ache for months, and its significance, disease of the vertebræ, was recognized only a short time before the patient came under the speaker's observation. There was no evidence of pulmonary disease in either of the three cases. Tinnitus and slight impairment of hearing were the first symptoms noticed.

In two of the cases, which were examined at an early period, there was slight redness and swelling at the upper part of the membrana tympani, and of the skin covering the bony wall. In a short time, the infiltration extended into the entire posterior superior quadrant. The membrane became bulging, and at the most prominent point a perforation established itself.

Following this, the disease followed a somewhat different course in the different cases. In one the redness spread, and other portions of the membrane became involved. In the case where spinal disease coexisted, the upper posterior portion of the canal became more congested, as though the bone were the seat of the disease. In the last case there was gradual improvement. The hearing was slightly impaired. In the other two cases, discharge became profuse. In one case, sudden hæmorrhage from the lungs occurred.

In the incipient stage, the distinguishing features are the tendency to localization in the upper posterior portion of the membrana tympani, the marked insignificance of the pain, or even its entire absence, and the intolerance to all but the simplest local measures.

The author read a communication from DR. CLARENCE J. BLAKE, of Boston, describing similar cases.

DR. SEXTON. I have seen many of these cases of catarrhal inflammation of the middle ear in phthisical subjects. The tendency of the structures of the ear to break down in advanced phthisis is very great.

DR. E. GREUNING, of New York. I have seen a number of cases, in which I was led to infer that the ulceration of the drum-head was due to tuberculosis. I distinctly recall three cases. In one case, that of a young man, only one ear was affected. The opening was in the inferior posterior quadrant of the drum-head. There was very little purulent discharge. There were two openings, showing that this was not the result of perforation from accumulation. It appeared to be a melting-down process. In another case there were multiple openings, so that the membrane appeared to be honey-combed. These, also, were in the membrana tympani proper. These cases improved under treatment, but the openings remained.

DR. C. R. AGNEW. I have seen a number of cases, in which I supposed that the origin was tuberculosis. In a considerable number of these cases, the main lesion has been in the drum-head, below the extremity of the handle of the malleus. I recall the case of a young man, who had trouble at the apex of both lungs when he came under observation. He stated that a short time previous, he had begun to have slight ringing and a sense of dulness in the ear; that this had gone on for two or three days; and then, when blowing his nose, he found that he whistled through his ear. In the ear complained of I found an opening, looking as though it had been removed by a punch.

The opening was eliptical. Within a few days, the same thing occurred in the other ear.

Dr. J. A. Andrews, of New York. In regard to the presence of the bacillus in middle-ear trouble occurring with phthisis, although I have examined a large number of cases, and some with a great deal of care, I have never found the bacillus.

Dr. A. H. Buck. I have not looked for the bacillus, but even if they are not found, tuberculosis should not be excluded, for their chances to escape detection are too numerous. I have seen cases like those described by Dr. Greuning, but I have not seen them in the early stages, and have, therefore, not considered them in my paper, as there is a possibility that they were due to previous ear disease.

Dr. J. Orne Green, of Boston. I have been much interested in this paper, and I recognize several characteristics which I apply to tuberculosis. Where I find this destruction coming on without pain and without discharge, I at once suspect a tubercular diathesis, and I generally find a history of it. I also agree with the speaker that only the very mildest measures can be used. Strong applications make the trouble worse.

Twice, in cases of advanced tuberculosis, I have seen, on examining the drum membrane, little white, glistening points about the size of a pin-head, not secreting at all, and in one case, with no congestion. In both cases, the spots disappeared in a few days, and within twenty-four hours there was a little clean, punched-out opening in the drum membrane. This occurred without any discharge. It seemed to me that I was dealing with isolated tubercles in the tissue of the drum membrane. One of these cases died a few months later from the general disease.

Certain Technical Details Relating to Operations on the Mastoid Process,

by A. H. Buck, M.D., of New York.

The speaker first referred to the objections which had been made to the drill. It has been stated that there is danger of plunging the drill into the lateral sinus, or even into the brain. He had, however, found no tendency for the drill to go astray. It had been said that the opening made was too small, but any sized drill might be made. He used a drill one-fourth of an inch in diameter until the antrum was reached, and finished the operation with a smaller drill. This gives a sufficient opening for drainage. Where there is a large sequestrum, it is necessary to make a larger opening.

After the use of the drill, pyæmia and septic fever is rare. With a knowledge of the part to be operated upon, the drill may be used with perfect safety. It can be guided perfectly by resting the fingers on the bone. The conical shape of the drill also enables the operator to tell when its point has entered a cavity.

The objections to the use of the chisel were next taken up. When this is used, the wound in the adjacent soft parts must be larger, and the opening in the bone is more extensive, leading to a depressed cicatrix. More time is required in the operation, and it is not free from danger. These objections are, however, trifling, if the results of the operation are found to be more satisfactory than those following the use of the drill. A study of the statistics of both methods seems to show that there is nothing to warrant the statement that chisels and gouges are to be greatly preferred to drills in establishing opening into the mastoid process.

In operating with the drill, after making the opening, I cut out a little canal for the escape of the discharges, for the opening made by the drill is covered by the flap when it comes into position. For the first four or five days after the operation, the wound is irrigated once a day with a bi-chloride solution, one to two thousand.

In reply to a question, Dr. Buck said that is his earlier operations, he applied the drill a short distance in front of the vertical line. His present plan is different. A straight vertical incision three inches long is made. By this means he exposes the mastoid process where it curves into the meatus. The drill is then applied to the first flat surface. The only difficulty is in establishing the final communication between the canal and the antrum.

Dr. J. Orne Green. In my practice I have used the drill almost entirely. I prefer to make a small opening at first and I am then guided by what I find. Some cases require a large opening, and in such cases the gouge and chisel will come into play. In the majority of cases a small opening is sufficient.

In some of these cases the use of the dental engine is very applicable. I have a modification of the engine which may be screwed to a table; it is turned by a handle, and any one can furnish the power. No skill is required, as in the engine worked with the treadle. Used in this way, I have found the engine of great service. The burrs can be used with the greatest delicacy. In the cases which I have operated on, I have put in a drainage tube and kept it in as long as possible. In the after-treatment I have used a solution of carbolic acid, one to eighty. Of late years I have applied an antiseptic gauze dressing and kept that on.

Dr. H. Knapp, of New York. I wish to make some remarks in favor of the chisel. In my first operations I used a drill, but I have abandoned it. With the chisel you can at every step observe the condition of the tissue which you are cutting. With the chisel you have a perfectly smooth surface, rendering it easier to cleanse the wound. It is also very easy to manage the chisel. The principle reason in favor of it is, however, that it enables each step of the operation to be seen.

Dr. H. D. Noyes, of New York. There is much less danger in the use of the chisel than of the drill. There is often great differences in the anatomical relations of the parts. The lateral sinus is not always found in the same place. With the drill, there is danger of perforating the walls of the sinus or of some important vein. With the chisel or the gouge, you explore the part, layer by layer, and ascertain how the parts are situated. This is a strong argument in favor of this instrument.

Dr. J. A. Andrews, of New York. In my operations, I have always used the chisel, but have always begun with the drill. I believe that the chisel is the best instrument and can be used with more caution than the drill. I always make a large opening, for I believe that a collection of pus should always be given free vent. Instead of the ordinary drainage tube I use a small rubber gutter to keep away the soft parts.

Dr. E. Greuning, of New York. I have opened the mastoid process seventy-seven times. At first I used the drill, and in acute cases the results were all that could be desired. The drill was, however, not applicable to all cases and I have since used the chisel. A small opening may be made with the chisel. What

can be done with the drill can be done with the chisel.

DR. A. H. BUCK, of New York. From the direction which the discussion has taken, it might appear that I am in antagonism with the chisel. I am not in antagonism with the chisel in those cases where a large portion of bone is to be removed. I leave those out of consideration in my paper. Where a large mass is to be removed it cannot be removed with the drill. The two instruments cannot come into conflict.

A communication with reference to the organization of a congress of American physicians and surgeons, was presented and referred to a committee consisting of Dr. C. R. Agnew, Dr. H. Knapp, and Dr. John Green to consider and report at the evening session.

The morning session was then adjourned.

EVENING SESSION.

FATAL TERMINATION OF A CASE OF SCLEROSING MASTOIDITIS AFTER CHISELING OF THE BONE.

by H. KNAPP, M.D., of New York.

A man, aged fifty, had extensive suppuration in both ears after scarlet fever in childhood. The right ear became totally deaf and the left, very hard of hearing, became deaf (hearing reduced to a quantitative perception of sound) by a recent attack of dizziness. Dr. Knapp found both tympanic membranes absent, the cavities sclerosed in both, pale in the right but congested in the left ear. Behind the left ear was found a cavity fully an inch deep, lined with immovable skin, the result of former exfoliation of bone. Three weeks later facial paralysis on the left side occurred. It disappeared in two weeks, under steaming and large doses of iodide of potassium. Two weeks later the patient suffered with constant intense headache and nausea. The mastoid was opened to the depth of half an inch by chiseling. The bone was compact and in the depth very vascular. During the first two days the patient was sleepy; could not be roused on the third, and died comatose on the fifth. No autopsy was allowed.

Death was due to traumatic meningitis. In regard to opening the bone in sclerosing mastoiditis: the prognosis is good when the sclerosis is the result of catarrhal or plastic inflammation, but bad when it was the consequence of old caries or necrosis. There are cases on the border line, and even when the prognosis was bad, the indications might be strong. The operation will rescue a certain number of the otherwise fatal cases.

A CASE OF ABSCESS OF THE MASTOID CELLS WHERE THE CHIEF INDICATION FOR OPERATION WAS ELEVATION OF TEMPERATURE,

by O. D. POMEROY, M.D., of New York.

A. S., age twenty years, fairly robust, had a violent attack of otitis of the right ear, which came on January 30, 1886. The following morning there was free discharge. February 1st, he entered the hospital, when a large perforation was found: a poultice and warm douches was ordered. By February 4th, the membrane looked almost normal. There was some pain in the occiput and a temperature of 103.6°. Ten grains of quinine with twenty grains of iodide of potassium, to be repeated in three hours, was ordered. This was followed by a reduction of two degrees in the temperature. The following day the temperature again went up, and it was apparent that a purulent process was going on. There was no swelling over the mastoid, and the pain was no greater than might be expected from a neuralgic condition.

After consultation it was decided to open the mastoid process. A drill was introduced and from four to six drops of pus evacuated. After the operation the patient continued to improve until he was discharged cured.

DISCUSSION.

DR. J. A. LIPPINCOTT, of Pittsburgh. In connection with Dr. Knapp's case, I should like to report a recent case in which an operation in a similar case resulted in failure. Something over two years ago I operated in a case of sclerosing mastoiditis, which had been suffering intense pain for twelve months, and which did not yield to alterative and tonic treatment. After the operation the patient remained well for thirteen months. The pain then returned and continued in spite of all treatment. Last March a second operation was performed, and a larger opening with the drill made. No benefit was produced.

DR. H. KNAPP. I should like to state that the cases which I have reported where benefit followed chiseling open a sclerosed mastoid, have remained well.

TWO CASES OF CHRONIC PURULENT INFLAMMATION OF THE ATTIC OF THE TYMPANUM WITH PERFORATION OF THE MEMBRANA FLACCIDA TREATED WITH PER-OXIDE OF HYDROGEN,

by CHARLES H. BURNETT, M.D., of Philadelphia.

In the first case no application had had the same good effect as the peroxide of hydrogen. Every other medicament had seemed to irritate rather than heal the inflammed mucous membrane. In the second case, the discharge, which had been very chronic, was promptly checked by the use of the peroxide of hydrogen.

The chemical formula of this drug is H_2O_2, and by its affinity for albuminous matters, especially those of pus, it seeks every particle of this matter in a cavity like the middle ear and thoroughly cleanses the parts. The union with pus is shown by a copious foam, which boils out of the external ear. When the foaming ceases and the peroxide returns clear, the diseased cavity has been thoroughly cleansed. In many cases this seems sufficient to effect a cure. Where there is a perforation in the membrana flaccida, the application is made by means of the tympanic syringe, the long and slender nozzle of which is introduced through the perforation at the attic of the tympanum. The peroxide is used undiluted.

IN THE PHYSIOLOGY OF HEARING IS THERE AN OVERLAPPING OF EACH AUDITORY FIELD THE SAME AS IN BIOCCULAR VISION,

by WILLIAM S. LITTLE, M.D., of Philadelphia.

Cases of one-sided deafness afford the opportunity of mapping out the auditory field for one ear and it is found with the watch at two feet from the ear the tick can be heard about ten or fifteen degrees across the median line of the head. This gives more scope to hear sounds produced on the side of the head opposite the good ear. The tuning fork is not heard even up to the median line on the side of the ear tested. The watch has been used in making the observations. If the field of one ear reaches beyond the median line to

about ten degrees, we have when both ears are normal an over-lapping of each field to the extent of fully ten degrees on either side of the median line in front, above and behind the head. Each ear hears sounds in this area of twenty degrees. Outside of this area, each ear hears singly. By means of this, there is no need to turn each ear towards the source of sounds which reach the individual: the direction of sound is best found in this way for safety in walking and maintaining the erect position. Sudden loss of hearing on one side puts the sufferer to great annoyance, as the ability to determine the direction of sounds is in a measure, lost, the patient often looking in the wrong place when called. It is fully as perplexing, if not more so, than in a case of sudden loss of sight in one eye, making seeing dependent on one organ of vision.

The attempt to restore hearing should be directed not only to obtain hearing in a line directly in front of the ear, but also to increase the area of hearing in the affected ear or both affected ears, till it reaches, if possible, the coalescence seen in normal ears.

A PAPER ON TWO CASES OF EAR DISEASE DUE TO TRAUMATISM,

by Dr. Gorham Bacon, of New York, was read by title.

The society then went into executive session.

The proposition with reference to the organization of a Congress of American Physicians and Surgeons was discussed, and a committee of conference was appointed, consisting of Drs. C. R. Agnew, of New York, H. Knapp, of New York, John Green, of St. Louis, W. H. Carmalt, of New Haven, and George Strawbridge, of Philadelphia.

The officers for the ensuing year are as follows:— President, Dr. J. S. Prout, of Brooklyn; vice-president, Dr. Samuel Sexton, of New York; secretary and treasurer, Dr. J. J. B. Vermyne, of New Bedford, Mass.; committee on membership, Drs. Gorham Bacon, W. S. Little, and E. W. Bartlett.

The following were elected to membership;— Dr. J. B. Emerson, of New York; Dr. J. O. Tansley, of New York; Dr. J. L. Minor, of New York; Dr. Henry L. Morse, of Boston; Dr. Huntington Richards, of New York; and Dr. T. Y. Sutphen, of Newark, N. J.

The society then adjourned.

THE AMERICAN OPHTHALMOLOGICAL SOCIETY.

The Twenty-Second Annual Meeting of the Society was held at the Pequot House, New London, Conn., July 21st and 22d, 1886.

The meeting was called to order by the President, Dr. William F. Norris, of Philadelphia.

A communication with reference to the organization of a Congress of American Physicians and Surgeons was read and referred to a committee consisting of Drs. C. R. Agnew, Charles S. Bull, and B. E. Fryer, for consideration with instructions to report at the present session.

Dr. Peters, of New York, Dr. D. Hubbel, of Buffalo, Dr. E. Friedenberg, of New York, Dr. Carvelle, of Manchester, and Dr. Cutter, of New York, were invited to take part in the proceedings of the Society.

The first paper read was entitled:

PYOGENIC MICRO-ORGANISMS, WITH DEMONSTRATIONS AND EXPERIMENTS,

by Dr. H. Knapp, M.D., of New York.

Dr. Knapp made some general remarks with reference to the dependence of suppuration on certain kinds of micro-organisms, the pyogenic bacteria, of which pure cultures have been obtained during the past two years. He exhibited these bacteria in numerous test-tube specimens on agar-agar, and also under the microscope. He also exhibited slides of different tissues of the eyes that had been infected with these germs. He showed two rabbits which he had operated on for cataract, the day before, in the presence of members of the Society. Extraction had been made on the left eyes with clean instruments, and on the right eyes with instruments contaminated with staphylococcus pyogenus aureus. The left eyes were free from secretion. The wound of one eye in a doubtful, the other in a good condition, whereas the right eyes discharged matter profusely and were in a state of intense destructive inflammation. He then operated on two other rabbits in the same way. The four rabbits were examined the next day. The eyes were examined with much interest by the members. The right eyes in all were suppurating; the wounds of the left eyes in three of the rabbits were in good condition. In one of the first two rabbits, it was suppurating. This eye had become infected from the right eye of the other rabbit. They had been kept in the same box and the operator had found them with their heads in contact.

These demonstrations were made to draw the attention of the members to this new and important field of inquiry, and the speaker would be happy to furnish cultures of these organisms to any one who intended to make investigations in this department.

In reply to a question as to the best method of cleaning instruments, Dr. Knapp said that in the institutions in Europe the instruments are placed in an antiseptic solution. This, however, has the disadvantage of dulling the edge of cutting instruments. His experiments had shown him that simple washing with water in the case of smooth instruments, followed by friction with a clean towel renders them bacteriologically clean. Where an instrument has a groove or is at all rough, it is much more difficult to clean. Instruments, like forceps, may be put in the antiseptic solution. It must be remembered that in the majority of our operations a certain quantity of infecting material is required to produce any effect. Where there is a free escape of liquid from the wound the material is washed off, but where there is a sucking-in process the danger of infection is much greater.

Dr. B. E. Fryer, of Kansas City. There is one antiseptic which has lately come into use which would probably not interfere with the edge of cutting instruments. That is hydro-napthol. It has, however, not been sufficiently long under observation to enable us to say whether or not it will completely sterilize instruments. It has also occurred to me that chloroform would probably perfectly sterilize instruments.

Dr. Hubbel, of Buffalo. I would ask Dr. Knapp if there are not certain conditions of the eye which would favor infection of the wound after operation. I recently operated in a case of cataract in a man sixty years of age, where there had been a long standing

purulent inflammation of both conjunctivæ. I performed an iridectomy following it in two weeks with extraction. Both operations were entirely successful and without accident, notwithstanding the fact that there was a constant purulent discharge. The only antiseptic used was a solution of boracic acid.

DR. H. KNAPP. I think that a lachrymal discharge with a certain amount of conjunctivitis furnishes a favorable soil for the growth of bacteria. In operating in such cases, the discharge should be completely removed. As I said before, a certain quantity of the pathogenic bacteria are required to produce infection. I have pricked the cornea to one-third or two-thirds its depth and covered the wound with an emulsion of the bacteria. In only one out of every four or five cases did abscess develop.

DR. J. A. ANDREWS, of New York. I have frequently pricked the cornea and applied the staphylococcus pyogenus aureus and have repeatedly seen recovery follow without suppuration or inflammation. Mere contact with the microbe with the wound is not always sufficient to produces suppuration, especially in the case of the cornea where the discharge is liable to be washed off. Where the material has been introduced into the wound and kept there for a short time, I have never seen a failure.

In the cleaning of instruments, I use what I term an aseptic fluid. I procure clean water and boil it for some time. This I use for the washing of instruments. The principal value of antiseptic solutions in hospitals is I think because they furnish something you are sure is clean. The water is not always clean. I do not mean to be understood as saying that I use boiling water. I simply boil the water to render it aseptic.

AN ANALYSIS OF ONE HUNDRED CASES OF EXUDATIVE RETINITIS OCCURRING IN THE COURSE OF BRIGHT'S DISEASE.

by DR. C. S. BULL, of New York.

Only such cases were included in the report as had been examined by the writer personally and had been followed to their termination. All cases due to scarlatina or pregnancy were excluded. Out of five hundred cases examined only one hundred and three fulfilled these conditions. The ophthalmoscopic examinations were made by the author, and the urine was always examined. In fifty-four of the cases, both eyes were affected when the patient came under observation, and in ninety-three per cent., both eyes were ultimately involved. Hæmorrhages occurred in sixty-nine cases. In thirty-four cases, there were no hæmorrhages. The hæmorrhages were intimately connected with disease of the bloodvessels. Only one instance of color affection was observed.

The prognosis with reference to the duration of life is very unfavorable. The one hundred and three cases reported, were collected during a period of thirteen years. Of this number eighty-six have died, fifty-seven during the first year and twelve during the second. Seventeen were still living, but fourteen of these were seen for the first time within the last six months. One of these cases, however, was seen for the first time seven years ago.

A rather unusual complication was seen in four of the cases; that was the presence of sugar, as well as albumen, in the urine. The amount of sugar was variable.

DR. E. GREUNING, of New York. I have collected over one hundred cases of this affection, and I find that none of my cases have lived over two years after the diagnosis of retinitis albuminurica has been made out. In this class of cases, I have included only those in which the typical stellate changes were seen in the maculæ of both eyes. I have lately seen this appearance in the macula of one eye in a patient who presents no evidence of Bright's disease. This is the first time that I have seen this exquisite change without signs of renal disease.

DR. B. E. FRYER, of Kansas City. In these cases, albumen is occasionally absent from the urine for a short time. In two such cases I have found albuminose during the time that albumen was wanting.

DR. DAVID WEBSTER, of New York. I am satisfied that, in rare instances, these patients do recover their general health and may live indefinitely. Some years ago I examined the eyes of a clergyman, and found the typical appearances of retinitis brightii. He had been examined fifteen years previously by a competent observer, who found the same condition, and also found albumen and casts in the urine. I had the urine examined, and found a slight trace of albumen.

DR. O. F. WADSWORTH, of Boston. Where the retinitis albuminurica comes on during, or immediately after pregnancy, I have seen the stellate spots in the maculæ entirely disappear. I have also seen typical stellate deposits in cerebral tumor, and in what was supposed to be meningitis, but in which there was no albuminuria.

DR. E. GREUNING, of New York. The cases of retinitis brightii which we see in our offices differ very materially from those which we see in hospitals. The patients who consult the oculist are usually those with the small, contracted kidney, while the patients with the large white kidney find their way to the hospital.

DR. C. S. BULL, of New York. I wish merely to repeat what I said in my paper, that I exclude all cases where the albuminuric retinitis was due to scarlet fever or to pregnancy. I do not mean to say that the so-called stellate exudation in the region of the maculæ is typical of Bright's disease. I have seen it in intracranial tumor, and in cases supposed to be meningitis. Retinal exudation other than stellate I have seen not infrequently in cases of large white kidney.

(To be continued.)

— The Library of the Society for the Advancement of Medical Science at Tokio, Japan, has just been presented with 64 volumes of the Boston Medical and Surgical Journal, being from 1848 to 1879 inclusive, bound in half calf.

— A correspondent writes us that he has lately witnessed the triumph of linseed oil in the treatment of pruritus ani where all the classical remedies had failed. In the case of two patients who had been for several years sufferers from pruritus ani with a trifling erythematous eruption and no rectal complications that could be discovered, the free external use of linseed oil at bed time about the parts gave immediate relief, and thus far free inunction with this simple remedy has given complete exemption from the nocturnal annoyance.

Medical and Surgical Journal.

THURSDAY, JULY 29, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

THE DOCTOR AS PATIENT.

THE study of medicine, and personal devotion to the alleviation of suffering, does not insure the doctor against the ills common to all mankind; nor does an intimate acquaintance with the vagaries of the sick enable a physician to pass through his own trials with equanimity. In fact, the doctor is far from appearing at his best in the *rôle* of patient; he feels as much out of place on a sick bed as would a general officer if he were reduced to the ranks. He has been so long accustomed to command, that he finds it very hard to obey, at least, without some sort of a protest.

During his student days he was led astray by his imagination, which made him suffer from the ills of which he studied. He probably, at that time, convinced himself of the ease with which one exaggerates his own sensations, and learned to disregard his own feelings for the most part. Only in such a way as this can we account for the neglect in himself of those beginnings of disease which a layman would suppose would infallibly arrest a doctor's attention, as they certainly would in a second person: as it is, he usually disregards his early symptoms and goes about with a temperature higher than that of the patient whom he sends inexorably to bed. He hopes for the best in his own case, as in others, but he fails to prepare for the worst, as he advises his patients to do, for he uses up, by continuing his work, the strength he ought to reserve to carry him through the sickness, it needs no angel sent from heaven to foretell. Once fairly prostrate, it is usually the alarmed relatives who summon the doctor, rather than the patient himself.

And it is no light task for the brother physician who presides over his sick bed to care for the prostrate individual, who insists on discussing the method of treatment, and with a disordered imagination and weakened intellect, desires to sit in judgment on the conduct of his own case. The patient is apt to be sceptical as to the powers of the drug on which his friend and adviser relies. He suspects his friend of a want of candor in his bedside talk. The little talks outside his door, the ruses of his wife to gain a little private conversation with the doctor, excite his anger. He listens for the noise of the wheels after his friend has left the room and if the sound of his chariot is too long delayed he feels sure that the long suffering man is delaying at the door to tell what he "really thinks," and he takes pains to interrupt the conversation by some abrupt message; perhaps, if it happens to be evening, by saying that it is time to close the house for the night.

But if he is critical and somewhat sceptical, he learns to know his physicians by their steps, and even the roll of their carriages on the street; and no patient gives them a more cordial welcome, or parts with them more reluctantly. He feels sure that his memory of their kind attentions certainly must be longer than that of certain patients who, according to the familiar lines, whose truth is too often confirmed by experience, forget even the doctor's face when they have recovered.

He seldom escapes making himself disagreeable to his nurses. It is hard to convince him that it is his own fault that his food does not taste as it ought. He is indignant that his own kitchen cannot produce broth as good as that of his neighbor's; but the tales of his own peevishness, when he hears them after recovery, he can but believe are grossly exaggerated.

Nothing is more surprising to the doctor, when reduced to the position of patient, than to find that he himself is subject to like weaknesses as other members of the human family. The nervousness, for which, in others, he has had too little sympathy, shows itself in a thousand ways. The little noises impossible to avoid disturb him, and the children of his household seem most unruly. Most strange of all, and most humiliating in his remembrance afterwards, he even calls his doctor for nothing. He wakes from sleep, sure he is going to have a chill, or some equally unpleasant manifestation, and when, with grave face and careful attention, his hastily summoned physician has felt his pulse, taken his temperature, and sought for the signs of any possible complication, to inform him at the end that there is nothing to justify his fears, he admires, and is grateful for the patience that has borne with his apprehensions, but he feels great curiosity to know what his doctor says to himself as he goes home to resume his broken sleep; and most of all, he wonders at himself and mutters, "is thy servant a dog, that he should have needlessly disturbed a doctor's sleep?"

But especially trying to an invalid doctor, is a tedious convalescence. His knowledge of the possible complications and sequelæ gives a wide field of possibilities, over which his imagination wanders uncontrolled, and he is fortunate if he does not become a hypochondriac. He is pretty apt to partake of the lay fondness for talking about the unusual features his case has shown. If he thinks about the matter at all, he finds how difficult it is to know at what length to detail his symptoms to inquiring friends. Unless he keeps his tongue in due subjection, he is apt to realize that few men are really good listeners, and his kind

friends, when they are released from his story, may be excused if they say, "poor fellow, he needs bracing up." But really, there is some excuse for him if he is a little garrulous; personal experience of pain is different from looking on, but interested as he is in his own closer acquaintance with disease, his account of it differs little, in the ears of his medical brethren, from the story they have often heard before.

But a little personal experience of the sick bed teaches the doctor many things. He certainly learns that a sick man does not look upon things as a well man does, and his charity towards an invalid's whims is greatly increased. He cannot fail, too, to be touched and softened by the many kind inquiries and pleasant messages that come to him. Busy men come and sit down beside him as though the dearest object of their hearts was to see him recover; men who justly plead bodily infirmity as an excuse against the slightest exertion climb his stairs to express their sympathy, and patients who have seemed thankless and forgetful show that they needed only the opportunity to show their gratitude. And when the sick man resumes his place in life, he is pretty sure to have not merely an increased enjoyment in living, and a better idea of his fellowmen, but also a higher estimate of the value of his own profession.

A LIST OF THE PUBLICATIONS OF HARVARD UNIVERSITY AND ITS OFFICERS, WITH THE CHIEF PUBLICATIONS OF THE UNIVERSITY, 1880–1885.

THE Bibliographical Contributions, just issued from the library of Harvard University, and edited by Justin Winsor, the librarian, includes the publications of the University, and its officers for the period from September 30, 1880, to September 30, 1885. The titles are grouped under the head of publications relating to the University and afterwards under the names of the different authors, alphabetically arranged, and these lists, of course, include the literary work of the instructors of the Harvard Medical School.

It is often said that Boston physicians write very little; certainly the number of books whose authors claim residence in Boston is not very large. Perhaps that is because their knowledge of books is sufficient to show them how rare are absolutely new ideas. Let the reason be what it may, they have the reputation of writing somewhat less than the medical population of some other cities. It is, then, something of a surprise to see how large a number of titles in the Harvard Bibliography is comprised in the contributions of the physicians who make up the faculty of the Harvard Medical School.

The first title of medical interest is the "New Century and the new Building of the Harvard Medical School," which contains the address of Dr. Holmes, and the remarks of the other gentlemen who took part in the exercises of the dedication. Dr. Holmes figures again more distinctly, on a later page of the collection, as the author of various works, not always strictly medical in character, but which are known to have something of a medical flavor, and which are carefully studied by the profession, not only in this, but in other lands, as any one may assure himself by reading the story of the poet's present wanderings.

The modern lithotritie frequently appears, not alone because the author's own name graces the list, but, as it would in any similar catalogue, because the subject has given rise to quite an extensive literature of its own. The subject is the basis of a title by nearly all the surgical instructors.

In the matter of clinical reports, the Bibliography shows an abundance of contributions, which often hide, under very modest titles, the results of careful observation. The number of contributions to encyclopædias and the amount of editorial work is also very large, and one who looks upon the encyclopædic articles as mere hack-work would greatly misjudge them: many of them are the result of personal experience rather than mere scholar's digests made in the library.

The number of articles representing work done in the physiological laboratory shows the encouragement to original research which is presented in that department. When one remembers the few years that such a laboratory has been adequately furnished, the results are exceedingly gratifying.

The object of this "List of Publications" we suppose to be two-fold, to show what has been done by the Faculty, and to stimulate the number of contributions in the future. The medical portion certainly contains some remarkable, and a large number of extremely creditable articles, but an attentive study will show that in many of the medical departments the literary production might be stimulated without great danger of forcing an over-growth.

THE SUCCESSFUL LEAP FROM THE BROOKLYN BRIDGE.

HANGING is said to have been considered by President Lincoln the worst use to which a man could be put: it is, perhaps, an open question whether a man subserves a better purpose who contributes to our knowledge of the results to the human frame of falls from great heights. If he kills himself in attempting to demonstrate his belief that he can safely jump from the Brooklyn Bridge he serves to point a moral, but if he succeeds, as the individual has done whose exploit has been so recently a subject of newspaper gossip, it is more difficult to know how to regard him. The JOURNAL has reason, however, to be grateful to the "hero of the fourth ward." A year ago, in commenting upon the fatal attempt of the late "Professor" Odlum, it ventured to say that "if they (the Sam Patchs and Odlums) could have struck the water squarely, feet foremost, they would doubtless not have been killed." "Steve" Brodie by *dropping* from the lowest wire instead of leaping from the rail succeeded in striking the water in that manner; and in fulfilling the necessary conditions, showed the truth of the JOURNAL's conclusions by surviving the fall.

The time of three seconds is stated to have been consumed in the transit: whether this statement is derived from accurate observation at the time, or from an abstract mathematical calculation we cannot say, but information seems to be reliable that the fallen body is in the receipt of one hundred dollars a week from an enterprising Dime Museum.

MEDICAL NOTES.

— An International Congress of Climatology and Hydrology is arranged to commence on October 1st, at Biarritz. A list of excursions into the Pyrenees and adjacent parts, which have been organized for the benefit of the members of the Congress, and which are spread out over the month of October, reaches upwards of thirty in number. Membership, the fee for which is fixed at 10s., confers the right to travel on the French railways at a reduction of fifty per cent., and entitles the member to join all or any of these excursions.

— The *Sanitarian* relates a case in which a rat had died under the floor of a large drawing-room, and was giving great offence to the owner of the house, who had had the carpets and furniture removed preparatory to taking up the floor. An ingenious friend drops in, suggests that the doors and windows be shut, steps out to the stables and traps a couple of blue-bottle flies, and returning, sets them free in the apartment. The flies, after a little undetermined buzzing, settled pertinaciously on a certain crack in the floor, and on the removal of one plank at this point, the cause of offence was readily removed.

— A case is reported from Port Elizabeth, South Africa, in which a man, while bathing had his leg completely bitten off by a shark; he was rescued, and, after immediate amputation above the condyles, recovered. On examination of the amputated stump there were distinct marks of the serrated edge of the shark's teeth on the outer condyle of the femur, two-thirds of which had been, as it were, sawn through; the monster must have caught the leg obliquely, crushed through the condyle and wrenched the leg off, going obliquely across the joint. There were also three wounds of the skin on the same side just below the rim of the pelvis, where the shark first caught his victim.

— Anything with a spice of horror in it has an attraction as a newspaper item. The following appears among the items of a daily paper:—

"A novel industry, to which a large manufactory in the suburbs of Paris is devoted, is that of preparing skeletons for the market. The proprietor contracts for a supply of corpses from all the dissecting-rooms and hospitals in the city, and the raw material is sent to him by the wagon load, to be dumped upon its arrival into huge cauldrons, in which it is boiled for days. When the contents of one of these cauldrons are sufficiently cooked, the grease is skimmed off, to be subsequently sold, and the soup having been poured away, the human fragments are laid upon a table, where the adhering tissues are carefully removed by the "bone peelers," as they are called. The bones are then bleached in the sun, and ultimately pass into the finishing room, where they are assorted and converted into articulated skeletons. To choose from the miscellaneous collection bones wherewith a skeleton may be constructed, which will pass for that of a single individual, requires no small amount of ingenuity. A female skeleton is worth several francs more than that of a male.

"The disarticulation of the skulls is performed separately, as it is a branch requiring greater skill and nicety in its manipulation. It is effected on the skulls of young adults or children by the ingenious plan of filling the emptied cranial cavity with dried peas, which are then steeped in water, and, in swelling, compel the disjunction more delicately than could be done in any other way. In some of the vats the bodies of infants only are boiled, and in the show-rooms of the establishment the skeletons of children are beautifully arranged in a graduated scale from minus four months up to three years. Other cauldrons are used for the bodies of animals, whose skeletons are valuable to the students of natural history. These are sold in great numbers to schools and colleges. The preparation of frogs, lizards and various reptiles occupies a separate department. The comparative cheapness and abundance of the skeleton supply from Vienna since the Russo-Turkish war has somewhat depressed the trade, but really good osteological preparations always command a high price."

NEW YORK.

— In a suit brought by the Society for the Prevention of Cruelty to Animals, of Jersey City, against Dr. Beriah A. Watson, a surgeon of eminence of that place, to recover damages for alleged cruelty to dogs in experimental surgery, Justice Lane gave judgment July 20th, against Dr. Watson, and an appeal is to be taken to the Court of Common Pleas.

— At a meeting of the Board of Managers of the St. John's Riverside Hospital, at Yonkers, held July 19th, the resignation of the visiting medical and surgical staff, which were recently tendered because of the failure of the board to appoint Dr. Edgar M. Hermace, a consulting physician, were accepted; while at the same time resolutions were adopted acknowledging the faithful service of the staff, and expressing the regret of the managers at their resignation. The resolutions also asserted that the reason for the failure to appoint Dr. Hermace was the fact that he had been ungentlemanly in his treatment of the Ladies' Committee and of the Board of Managers.

— Dr. Alfred S. Purdy, one of the oldest and most highly esteemed practitioners of the city, died of pneumonia on the 22d of July, at his residence, No. 308 Madison Avenue. He was born in New York in 1808, and commenced the study of medicine in the office of Dr. Alexander H. Stevens, a noted surgeon of the day. He was graduated from the College of Phy-

sicians and Surgeons in 1834, and continued in active practise in his native city for fifty-five years. His funeral, which occurred July 24th, was attended by delegations from the New York Academy of Medicine, the Medical Society of the County of New York, and the New York Pathological Society, of which societies he had been a member for many years. The services were held at St. Paul Methodist Episcopal Church, of which he was one of the founders, as well as a trustee, at the time of his death.

— In Troy there would seem to be an admirable opportunity for the enforcement of the existing statutes against the illegal practice of medicine. A certain Mrs. Hoyt, of that city, some time ago obtained a diploma from an institution known as the "American Health College," of Cincinnati, claiming, it is said, to be incorporated under the laws of Ohio, which authorizes her to practice the "vitapathic system of medicine," whatever that may be. She states that she was graduated from the college after an attendance of *eight weeks* upon its course of study, and that she also has a certificate from the institution authorizing her to perform the functions of a minister of the Gospel. Acting upon the powers conferred by the latter, it is asserted that she has already officiated at two marriages; but to what extent she has inflicted the "vitapathic system of medicine" upon the community has not transpired.

Miscellany.

MEDICO-LEGAL CASE — ALBINO BIRTH — IS IT WHITE OR BLACK?

READERS of the JOURNAL who read "Mr. and Mrs Morton" cannot fail to find interest in the following letter which originally appeared in the *Virginia Medical Monthly.*

MR. EDITOR,— At a recent term of the Corporation Court of this city, a case involving legal medicine occurred of sufficient interest to justify a short account of it.

William H. Brothers and Sarah E. Brothers, both negroes, were married some years ago and are the parents of two children, a boy and a girl. On November 4th, 1883, after many quarrels, they parted, and in April, 1884, Sarah E. Brothers obtained a decree of absolute divorce against her husband, Wm. H. Brothers, and the chancellor gave to her, the plaintiff, the custody of the children, and imposed upon her the care of their property, consisting of some city real estate.

On August 6th, 1884, nine months and two days after last opportunity of access, Sarah Brothers was delivered of a white child. Becoming aware of this fact, Wm. H. Brothers entered a petition before the court to have his two children removed from the custody of their mother and their property remanded to other care, alleging that the fact that her child was white was sufficient proof that he, a negro, was not the father of the child, and therefore proof of the adultery of the mother. She resisted the petition, declaring that the child was the offspring of the petitioner and an albino. After the case had been in court many months, the chancellor declined to decide the parentage of the child, and a jury was called to determine "Whether W. H. Brothers is the father of the child of Sarah E. Brothers, born on August 6th, 1884."

On the trial the child was produced in court; opportunity of access was proven as late as the 4th of the November preceding, the motherhood was proved, and I was called upon to testify as to the race.

I found a child of skin as white as pearl — glistening, smooth and very thin — hair woolly but perfectly white, eyes light gray with pinkish pupils, oscillating continually, nose flat and thoroughly African, head heavily developed behind, low forehead, rather rounded, lips thin. I had therefore no hesitation in declaring the child to be an Albino. Then came the question is it a negro or mulatto albino? I concluded that the "kinky" wool and flat nose were sufficiently marked to demand the opinion that it was not a mulatto; but what was I to do with those thin lips? At last I concluded that the thinness of lip was probably due to the atavism or the reversion to strain, and that possibly there was a trace of white blood somewhere in one or other of the parents. The mother was pointed out to me, and I thought that I could see that she was not a full-blooded negro. The two undoubted children of the contestants were now presented in court, and I was pleased to find both of them the possessors of thin lips. Wm. H. Brothers was shown to me, and I found he had the same sort of lips, and undoubtedly had white blood in his veins. I had seen the child before, but never any other member of the family. I pointed out each feature to the jury and discussed it before them, and called their attention to the lips as the only feature which prevented me from asserting that the child was a full-blooded negro, and then pointed to the lips of the other members of the family.

After argument, the jury retired and soon returned with the verdict, "We the jury, find that W. H. Brothers is the father of the child of Sarah E. Brothers, born on August 6th, 1884."

WM. A. THOM, JR., M.D.

NORFOLK, VA., May 31st, 1886.

HYDROPHOBIA AND PASTEUR. TWO OPPOSING STATEMENTS.

The first is practically the substance of a special despatch to an enterprising daily:—

"Henry Bergh, the man who prevents cruelty to animals in New York and vicinity, is taking an interest in the case of the young man Harold Newell, the son of a Jersey City doctor, upon whom Dr. Valentine Mott has been 'experimenting, after the Pasteur fashion, to cure him of a dog bite.' He said to a reporter to-day that 'Dr. Mott and the rest of them ought to be arrested. He is probably acquainted with Pasteur's financial success, and is making this an experiment advertisement for future operations. The whole principle of inoculation is wrong. The medical profession fears to express its honest convictions because of the popular belief in vaccination. The human race is deteriorating under vaccination. Smallpox, cancers, tumors, syphilis and other forms of disease are resulting from it. There are no end of fanatics who

find microbes for every disease. They will be finding one for delirium tremens before long. There is no proof that Pasteur has ever cured a patient of hydrophobia, for there is no proof that he has ever had a hydrophobia patient. He has bulldosed his countrymen, the government has subsidized him, and the people take what he gives them. He has insulted common sense. What healing power is there in veal broth injected into the blood? Can anything be more absurd than this taking virus from a diseased sore and putting it into the veins of a healthy person?'

"The experiments on young Newell were temporarily suspended because it was feared they were giving him hydrophobia, instead of curing him of it."

The second is the account from an honored medical contemporary of a lecture in which M. Grancher, the collaborator of M. Pasteur, presented, for the first time, the clinical history of the patients treated for hydrophobia by vaccination. The persons bitten and vaccinated were grouped in three classes:—

"(1) Those bitten by a dog of which the nervous system was sent to Pasteur's laboratory, inoculated in rabbits, and caused death of the latter by hydrophobia; or those who had been bitten by a dog the bite of which had caused death by hydrophobia in other animals or man.

"(2) Those bitten by a dog which before or after death had been examined and declared rabid by a veterinarian.

"(3) Those bitten by a mad dog which had escaped observation.

"The statistics extend to April 22, 1886.

"The total of the three categories includes 1,335 patients. Elaborate and rigorous statistics prepared by M. Leblanc, Member of the Academy of Medicine and Veterinarian to the city of Paris, show that of 100 non-vaccinated persons bitten by rabid animals, 16 die.

"In the first group above mentioned there were 96 patients, of which 1 died, a mortality of 1.04 per cent.

"In the second series are 644 subjects and 3 deaths, a mortality of 0.46 per cent., or for the two series, of 0.75 per cent.

"In the third series are 232 cases, which are here disregarded.

"The mortality among patients bitten on exposed surfaces (the face and hands), was in the first group 54, with 1 death, mortality 1.8 per cent.; in the second group, 400 with 3 deaths, mortality 0.75 per cent. M. Brouardel, in examining the statistics of the Council of Hygiene from 1862 to 1872, finds that in non-vaccinated persons bitten on exposed surfaces, the mortality is 80 per cent.

"In addition, M. Pasteur has vaccinated 48 persons bitten by mad wolves; of these 7 have died, giving a mortality of 14 per cent. M. Brouardel has shown that non-vaccinated individuals similarly bitten present a mortality of 66.5 per cent.

REPORTED MORTALITY FOR THE WEEK ENDING JULY 17, 1886.

Massachusetts Towns	—	—	—	—	—	—	—	—

Deaths reported 2,510: under five years of age 1,379; principal afections diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 925, consumption 235, lung diseases 158, diarrhœal diseases 720, diphtheria and croup 85, whooping-cough 27, scarlet fever 24, measles 20, typhoid fever 19, malarial fever 17, cerebro-spinal meningitis 14, puerperal fever two. From scarlet fever, St. Louis six, New York and Pittsburgh five each, Cincinnati three, Cambridge, Brooklyn, District of Columbia and Waltham one each. From measles, New York nine, Baltimore four, Cincinnati three, Brooklyn, Pittsburgh, Nashville and Worcester one each. From typhoid fever, District of Columbia five, New York and Cincinnati four each, St. Louis and Nashville two each, Baltimore and Pittsburgh one each. From malarial fever, St. Louis five, New York four, Brooklyn, Baltimore and Nashville two each. From cerebro-spinal meningitis, New York eight, District of Columbia and Nashville two each, Fall River and Holyoke one each. From puerperal fever, Brooklyn and Boston, one each.

In the 20 cities and greater towns of Massachusetts, with a population of 956,052 (population of the State 1,941,465), the total death-rate for the week was 21.27 against 18.76 and 18.02 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,033,817, for the week ending July 10th the death-rate was 18.4. Deaths reported 3,213: infants under one year of age 907: diarrhœa 225, measles 116, whooping-cough 58, scarlet fever 33, fever 27, diphtheria 18.

The death-rates ranged from 25.2 in Preston to 11.7 in Wolverhampton; Birmingham 15.0; Hull 15.3; Leeds 19.5; Leicester 14.6; Liverpool 18.2; London 19.4; Manchester 20.1; Nottingham 18.5; Sheffield 15.1; Sunderland 13.1.

In Edinburgh 20.5; Glasgow 18.9; Dublin 23.1.

For the week ending July 10th, in the Swiss towns, there were 29 deaths from consumption, lung diseases 23, diarrhœal diseases 10, measles five, diphtheria and croup three, puerperal fever two, small-pox and erysipelas each one.

The death-rates were: at Zurich 9.9; Geneva 17.2; Basle 11.8; Berne 21.4.

The meteorological record for week ending July 17, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, July 17, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 17, 1886, TO JULY 23, 1886.

PERIN, GLOVER, assistant surgeon general and colonel. Leave of absence extended one month. S. O. 165, A. G. O., July 19, 1886.

GARDNER, WM. H., major and surgeon. Granted four months leave of absence, to take effect August 10th, or as soon thereafter as his services can be spared. S.O. 165, A. G. O., July 19, 1886.

DE WITT, CALVIN, major and surgeon. Assigned to duty at Fort Sully, Dak. S. O. 66, Department of Dakota, July 14, 1886.

BARNETT, RICHARDS, captain and assistant surgeon. Leave of absence extended six months on surgeon's certificate of disability. S. O. 156, A. G. O., July 15, 1886.

KANE, J. J., captain and assistant surgeon. Ordered from Fort Ringgold, Tex., to Fort Hancock, Tex. S. O. 85, Department of Texas, July 13, 1886.

CARTER, WM. F., captain and assistant surgeon. Ordered from Fort Concho, Tex., to Fort Ringgold, Tex. S. O. 85, Department of Texas, July 13, 1886.

DICKSON, JNO. M., captain and assistant surgeon. Ordered from Alestrag Island, Cal., to Fort Mason, Cal.

COCHRAN, JNO. J., captain and assistant surgeon. Ordered from Fort Mason, Cal., to Presidio of San Francisco.

GIBSON, R. J., captain and assistant surgeon. Ordered from Fort Winfield Scott, Cal., to Alestrag Island, Cal., on return from leave of absence. S. O. 56, Department of California, July 8, 1886.

OWEN, WM O., JR., first lieutenant and assistant surgeon. Ordered for duty at Fort Schuyler, New York Harbor. S. O. 84, Division of the Atlantic, July 15, 1886.

Relations of the State and the Medical Profession. An Address Delivered before the Alumni Association of the Department of Medicine and Surgery of the University of Michigan. By Charles J. Lundy, M.D. Reprint.

Lecture.

ON COMPLETE ALIMENTS AND ON THE MILK DIET.[1]

A CLINICAL LECTURE ON HYGIENIC THERAPEUTICS.

BY PROF. DUJARDIN-BEAUMETZ, M.D., PARIS, FRANCE.

GENTLEMEN: — My last lecture was concerned with the primordial alimentary principles (albumen, fibrin, sugar, salts, etc.) No one of these *per se* can suffice for sustenance, and it is only in a state of combination that they constitute food. The number of alimentary substances that contain these proximate principles associated in the proper proportion to subserve all the necessities of nutrition, is, as you know, very limited, in fact, milk and eggs are almost the only complete aliments. With regard to ordinary foods, the alimentary principles are unequally distributed through them, and it is only by combining foods of various kinds that we have a dietary capable of meeting all the wants of the economy. Hence the division of foods which I have before given you into complete and complex aliments.

Milk has to-day an important therapeutic *rôle*; it is in fact a food medicine which renders us great service in a large number of diseases. I shall therefore devote this lecture to the consideration of milk diet, concluding with a few words about eggs and their employment in alimentary hygiene.

Milk is the type of complete aliments, containing in its composition (the gelatinous substances alone being excepted), all the primordial principles in large proportion. The albumen and casein represent the albuminoid principles; the butter represents the fats; the sugar of milk the carbo-hydrates, and the whey contains the water and salts which stand for the inorganic principles; two alkaloids have also been found in milk, if we may trust the experiments of Winter-Blyth; galactine and lacto-chrome. But these researches have not been confirmed, and we may say the same of those still later investigations, whereby casein has been shown to have a multiple albuminoid composition, (Hammesten, Radenhausen, etc.)

The table which I here place before you shows you the *average* composition of the milk of the human female, the ass, the cow, and the goat. (Henri Fery.)

Milk in 1000 Parts.	Woman.	Ass.	Cow.	Goat.
Density. . . .	1033.50	1032.10	1033.40	1033.85
Water	9009.10	9149.00	9109.08	8698.52
Dry Extract . .	133.40	118.10	125.32	164.34
Butter	43.43	20.10	34.00	60.00
Sugar	76.14	69.30	52.16	48.56
Casein	10.52	12.30	28.12	44.27
Salts	2.14	4.50	6.00	9.10

By glancing over the above table it will be seen that if the density varies but little, oscillating between 1032 and 1033, and if the proportion of water remains about the same in the several kinds, being expressed by a mean of 900 grammes, it is not so with the other principles of milk and particularly with the butter, lactose and casein.

If the milk of the human female and that of the ass resemble each other in the quantity of casein which they each contain, they differ very much in this respect from that of the cow and the goat which contain twice and three times as much, (28.12 for cow's milk, 44.27 for goat's milk). As for the sugar, the ratio is the reverse, this principle existing in less quantity in the milk of the cow and goat, as the table shows. As for the butter, it is the goat's milk which takes the precedence, while that of the ass contains the least.

The Municipal Laboratory of Paris, which has rendered such great service in the prosecution of frauds and sophistications of milk in this city, has established the following mean for cow's milk, below which the milk is considered bad.

One hundred parts of milk ought to yield the following substances in the following proportions:

Water		87.00
Extract (by heat maintained at 95°) . .		13.00
Ashes	.60	
Butter	4.00	
Lactose	5.00	
Casein	3.40	
		100.00

Chief importance in this analysis should be assigned to the figure of the extract, which should not be under 13 per cent. This is the proportion found by Carter Bell in England and Dr. S. W. Abbott, of Boston, (see especially the excellent report of the latter on the Milks of Massachusetts, published the present year).

But the above estimate must be considered only as a fair average, and milk, from whatever source, will present numerous variations, according to the age of the animal, the state of fatigue or repose, according to the time the milk has remained in the udder, frequency of milking, etc. But the food of the animal or nursing woman has the principal influence on the composition of this liquid, and this leads me to speak of medicinal milks.

Medicines may in fact be eliminated in the milk, and during the past few years important researches have been made which concern this very point: I will call your attention more particularly to those of Thomas Dolan,[2] of Pauli, and Lewald,[3] of Kehler, of Lazansky, of Fehling,[4] of Max Stumpf, etc.

It has been proved that medicinal and toxic substances derived from plants pass out in great part in the milk. It is well known that the solanum alkaloids may render the milk toxic to the infant. As for mineral substances, a great number are excreted in the milk. Thus the milk may become impregnated with iodine and iodide of potassium by giving these medicinal agents to nursing women. It is so also with salicylic acid, and it is known to be dangerous to give very large therapeutic doses of arsenic to wet-nurses; Brouardel and Pouchet, in fact, report a case where it appears that the death of the infant was the result of such administration. Although Keller has maintained that mercury is not eliminated by the milk, except when given in poisonous doses, all experimenters are of opinion that the mercurial preparations when taken in therapeutic doses by nursing women may pass out in the milk, and that syphilitic infants may in this way be treated.

There is the same general agreement with regard to quinine. Instances have been cited of nurslings being cured of malarial fevers by quinine given to the wet-nurse and passing out in the milk. As for alcohol, it is never eliminated by the mammary gland, but it gives rise to milk of bad quality. This question has been often discussed in connection with the subject of the feeding of cows on the malt refuse of breweries.

[4] Journal of Obstetrics, 1875.

If milks may thus become medicinal or toxic by the fact of the administration of medicaments, they may also become the factors in the genesis of certain diseases by being the carriers of the germs of those diseases, and it has been claimed that in this way typhoid fever, tuberculosis and even syphilis may be transmitted. As far as syphilis is concerned, the experiments of Padova and Gallois have shown the perfect innocuousness of the milk of syphilitic wet-nurses, and if this disease is transmitted to the nursling, it is not by the milk that it is communicated but by mucous patches on the lips or nipples of the wet-nurse.

If typhoid fever has ever been propagated by milk, it was by the water fraudulently added to the milk by the vendor that the *materies morbi* was transmitted. It is known that the sources of drinking water are often contaminated by typhoid fever dejecta (as in the case of proximity of walls to cesspools), and dishonest milkmen have on some occasions adulterated their milk with such water, thus spreading the disease.

Moreover, there is no doubt that Koch's tubercle bacillus may penetrate the mammary secretion in tuberculous females, or cows affected with bovine phthisis; such milk has been proved capable of communicating tuberculosis when inoculated in animals susceptible to the disease (like hares).[5] Other animals as dogs, are incapable of being in this way rendered tuberculous. Most men show a similar resistance to the virulent principle; moreover, when milk containing the bacilli are taken into the healthy stomach, these micro-organisms are likely to be destroyed by the gastric juice.

It is also notorious that none are more exposed to emanations from tuberculous persons than physicians, who are often for hours in an atmosphere abounding in dried sputum particles, and if they resist the contagion, it is because their organisms are an unsuitable culture medium for the bacilli. As you see I do not believe much in the dangers supposed to arise from tuberculous milk, and there is at any rate an easy way of rendering such milk innocuous, namely, by boiling it.

Milk undergoes fermentation through the influence of a special organism, the *oidium lactis* or *bacterium termo*, the lactose being transformed into lactic acid, as the following formula shows:

$$\underset{\text{Sugar of milk.}}{C_{12}H_{24}O_{12}} = 4\underset{\text{Lactic acid.}}{(C_3H_6O_3)}$$

The lactic acid when formed causes the precipitation of the casein and the milk separates into two parts, the whey and the solid matters. Whey is very much employed in medicine, and you will see in Switzerland and in the Austrian Tyrol and other parts of Europe numerous stations where the "whey cure" is carried out.

Whey is composed principally of the salts, sugar, and a certain quantity of casein and of butter which has escaped precipitation. The following analysis from Valentiner gives you the composition of whey:

	Sheep.	Cows.	Goats.
Water	91.960	63.264	91.380
Albuminoid matters (albumen and casein)	2.130	1.080	1.140
Sugar of milk	5.070	5.100	4.530
Fatty matters	0.252	0.116	0.372
Salts and extractives	0.588	0.440	0.578
	100.00	100.00	100.00

The patients drink a small tumblerful, morning and evening, increasing the quantity until ten or twelve a day are taken. During the whey treatment they are compelled to submit to a rigorous dietetic regimen, which consists principally in abstinence from meat and in the use of vegetables and fruits; moreover, they are required to take regular exercise in the open air. Whey has been very much vaunted in the treatment of certain affections, and particularly phthisis and dyspepsia.

It is especially in the dyspepsia of high livers that the whey treatment has furnished brilliant results, and these are in my opinion due more to the good air which the patient breathes and the daily walks which he takes and the rigorous diet to which he is subjected than to the whey he drinks, which seems to me devoid of any very energetic therapeutic action.

Whey baths were formerly given; these have been abandoned on account of their cost. In fact, the skin covered with its epithelium does not absorb saline medicinal solutions, as you well know.

If the action of air on milk which has undergone the lactic fermentation be prolonged, a new transformation takes place under the influence of a new rod-shaped vibrio; I allude to the butyric fermentation. The lactic acid breaks up into butyric acid, carbonic acid and hydrogen.

$$\underset{\text{Lactic acid.}}{2(CO^2H^6O^3)} = \underset{\text{Butyric.}}{C^4H^8O^2} + CO^2 + H$$

Lastly, this butyric fermentation may give place to still another change, leading to the formation of leucine and tyrosine, ammonia, etc.; here you have the putrid fermentation. Cheese results from these two fermentations, the butyric and the putrid.

The following table will show you the richness of cheese in nitrogen. The Parmesan has the first rank. These figures explain how it is that a man can live on bread and cheese, since he finds in the latter aliment a notable quantity of nitrogen, fat and salts.

TABLE OF THE COMPOSITION OF CHEESES.

Cheeses.	Water.	Azotized Substances.	Fats.	Non-azot'd Substances.	Salts.
Blanc	68.760	19.989	9.429	6.032	0.810
Roquefort	34.550	26.520	30.140	3.720	5.070
Gruyère	40.000	31.5	24.00	1.5	3.00
Hollande	36.10	29.43	27.54	1.5	6.93
Neufchâtel	34.47	13.03	41.91	6.96	3.63
Camembert	51.94	18.90	21.05	4.40	4.71
Brie	45.25	18.48	25.73	4.83	5.61
Chester	35.92	25.99	36.34	7.59	4.16
Parmesan	27.56	44.08	15.95	6.69	5.72

All these fermentations take place more or less rapidly in milk, according to the temperature, and the cleanliness or want of cleanliness of the vessels which contain the milk. In fact, it requires but a small quantity of ferment to alter the milk, and this explains why it is that bottle-fed babies are so apt to sicken and die in the hot weather; according to Henri Fauvel the milk of nursing bottles is "turned" twenty-eight times out of thirty.[6]

Thus far, we have had to do only with the lactic fermentation, but the milk sugar may, like other sugars, undergo directly the alcoholic fermentation, and be transformed into alcohol and carbonic acid. There are three kinds of fermented milk; koumiss, kefir and galazyme. On the banks of the Caspian Sea and in the immense plains which surround it, the Tartar tribes raise innumerable troops of horses. It is mare's milk which is utilized; this is poured into a leather bottle containing a little old dried koumiss, then, whether the milk be beaten with a rod or the

[5] Klebs and Peuch.

[6] Academy des Sciences, 1881.

horseman uses his leathern bottle as a saddle, a fermentation takes place which results in the production of alcohol. This fermented mare's milk constitutes the koumiss which is distinguished as young or old koumiss according as the fermentation has been going on for a short or long time; the young koumiss having one per cent. of alcohol, the old two, and even three per cent.

You can judge of the modifications which this milk undergoes by the following analysis of Hartier:

Per 1000.	Mare's Milk.	Koumiss.
Albuminoids	19 to 28	11.20
Fatty Matters	12 to 15	12.00
Sugar of Milk	53 to 57	22.00
Lactic Acid	53 to 57	11.50
Carbolic Acid	53 to 57	7.85
Alcohol	53 to 57	16.50
Ashes or Salts	0.280	0.280

It is in another part of Russia, in the mountains of Caucasas, that kefir is made. Here a special substance is employed to ferment cow's milk, and which is now sold under the name of *Kefir grains*. This kefir grain owes its property to a microbe, the *dispora Caucasica*, which induces the alcoholic fermentation of the milk.

We have here a confirmation of the brilliant theories of our illustrious countryman, Pasteur, who has shown us that each special fermentation is due to a special micro-organism, and while the *oidium lactis* transforms the sugar of milk into lactic acid, the *dispora Caucasica* changes it into alcohol. A few of these grains are put into a bottle of milk, and the bottle is tightly corked, and its contents are subjected to a constant temperature of 15° or 16° C., and a fermented milk very similar to koumiss is thus obtained, a milk, however, which is less rich in alcohol, which is explained by the fact that cow's milk contains less sugar than mare's milk. This kefir is also distinguished as young and old kefir, the one containing 60 centigrammes per 100 of alcohol, the other as much as 1.50 grammes per 100. The following analysis indicates the difference between cow's milk and kefir.

Per 1000.	Cow's Milk.	Kefir.
Albumin	48.00	38.00
Fats	38.00	20.00
Sugar of Milk	41.60	20.025
Lactic Acid	41.60	4.00
Alcohol	41.60	8.00
Water and Salts	873.00	904.975
Density	1028	1026

To explain the diminution of butter and albuminous substances, it is necessary to take note that the kefir was made with skim milk.

Under the name of *galazyme* Schneep has described certain kinds of milk rendered alcoholic by the addition of sugar and a special ferment. Schneep made use of brewers' yeast, to which he added three parts of cane sugar and five parts of sugar of milk, which, if supposed to represent grammes, are sufficient for a litre of milk. This formula has been more or less modified by Pigatti, of Trieste, who associates with brewers' yeast, honey, alcohol, and wheat flour. Adam Gibson adds sugar of milk and cane sugar to skim milk in the process of fermentation, while Wolff employs grape sugar and brewers' yeast. My pupil, Deschiens, has very happily modified these formulæ; he makes use of those improved ferments which are employed to-day in the fabrication of pleasant liquors, ferments which are known under the name of high malt yeast. This yeast, as you see, has no odor, and is of a bluish-gray color; take four grammes, add ten grammes of sugar, and dissolve them in a little water, and pour the whole into a litre of milk; the bottle is corked and the cork tied in, and the next day, you have a sparkling beverage which you can enjoy, and which contains one per cent. of alcohol and a great deal of carbonic acid.

All these fermented milks — whether you have to do with koumiss, kefir, or galazyme — are identical in composition; they contain alcohol, carbonic acid, lactic acid, and the other elements of the milk. Their richness in alcohol is always the same, and oscillates between one and two per cent. At the same time, you can easily understand that with the process of Deschiens you can augment the quantity of alcohol by increasing the quantity of sugar and ferment. These fermented milks are generally well tolerated, especially by stomachs habituated to alcoholic liquors. By their alcohol and lactic acid they add to the tonic and digestive properties of the milk; by their carbonic acid they calm pain and vomiting, and we have consequently derived from these "champagne milks" good effects in the torpid form of tuberculosis, and especially in the gastric catarrh of drunkards. These fermented milks also enable us to institute an exclusive milk diet for our alcoholic patients, while, at the same time, restricting to a minimum the usage of alcohol.

Before entering on the study of milk diet and its applications, I must say a few words about the digestibility of milk and its physiological action. When milk enters the stomach, its casein is precipitated under the influence of the acid of the gastric juice; then this casein is subjected to the action of the pepsin which liquefies it and renders it absorbable under the form of pepto-casein. As for the lactose, it undergoes the lactic acid transformation, and furnishes to the stomach an element useful for digestion, the acid which I have just mentioned. The salts and the water are absorbed principally in the intestine, and it is the presence of these salts in notable proportion which tends to diminish the intestinal secretion. Lastly, the butter and fatty substances are subjected to the action of pancreatine in the intestine.

Of all these digestive acts, there are two which you ought especially to keep in mind, namely, the action of milk on the stomach and intestine. As Charles Richet has well said in his admirable treatise on the gastric juice, milk is the regulator of the acidity of the gastric juice; when this acidity is lacking by reason of atrophy or destruction of the peptic glands, milk furnishes, by its lactic acid, an element necessary for the stomachal digestion. When, on the other hand, the acidity is too great, the precipitated casein carries with it a great quantity of this acid, and thus mitigates the evil. Of these two modes of action, the first is certainly the most important. It often happens, however, that certain stomachs, by reason of excessive acidity, tolerate milk badly, but you have always ready at hand a means of attenuating this acidity by mixing with the milk lime-water, or the natural alkaline waters.

The action of milk on the intestines renders milk of great value in intestinal complaints, as milk is one of the most active constipating remedies which we possess. Lastly, do not forget that each litre of milk contains nine hundred grammes of water, and this explains the powerful diuretic action of this aliment.

To sum up, from the point of view of its physiological and therapeutical action, milk presents itself under the four following aspects: it is a reconstituent food; it is a regulator of the acidity of the gastric juice; it

is a constipating medicament, and it is a diuretic. We will now consider the applications of these properties in the usage of the milk diet.

The milk treatment may be exclusive, and here the patient takes nothing but milk. In other cases, the regimen is a mixed one, and the patient takes, along with his food, a considerable quantity of milk. There is an important precept laid down by Karel. of St. Petersburg, namely, that it is not enough to tell a patient to drink milk, but you should also vigorously fix the rules of this treatment.

The quantity of milk to administer daily varies between two and three quarts. Maurel has shown that three quarts per day suffices for nutrition, and that patients lose weight when any less quantity is used.[7] This quantity ought to be taken in fractional doses, and every hour you should give the patient a small tumblerful (from four to six ounces). When the stomach is intolerant, you can give one-fourth this amount every quarter of an hour, as Galliard recommends. The milk may be drunk hot or cold, and even ice-cold. You can also, to increase the thirst of the patient, add a little salt to each glass of milk. I also advise you to "cut" the milk, according to circumstances, with a great spoonful of alkaline water (Vichy or Vals), or with the same quantity of lime-water. Some have pretended that these additions impair the digestibility of milk; it is not so, and I have always ascertained, on the contrary, that milk is more easily digested by reason of this admixture.

Milk passes rapidly out of the stomach, and I have always found, in the hospital experiments which I have made to test the speed of the digestion of milk, that at the end of an hour, in healthy stomachs, a pint of milk had completely disappeared from the gastric cavity.

In fixing, then, at two hundred grammes (between six and seven ounces) the quantity of milk which a person ought to take every hour who is living on this aliment, you will not be likely to go astray. These results are completely opposed to those which Reichmann has recently obtained.[8] This experimenter pretends that three hundred cubic centimetres of milk take three hours to pass from the stomach to the intestine. He pretends also that boiled milk passes more readily out of the stomach than raw milk. My own experiences as before said, do not confirm those of Reichmann. As I have found no difference between raw and boiled milk from the point of view of digestibility, I ought, however, to tell you that some authorities, and Pinard in particular, have claimed that prolonged boiling favors the digestibility of milk in peptonizing a part of the albuminoid substances therein contained. This is a point that demands farther investigation.

But whatever pains you may take to lay down the rules of the milk diet, you will often see your efforts fail by reason of an unsurmountable obstacle, namely, the disrelish of certain patients for milk. At other times the patient tires of the milk diet after persevering a while with this regimen. To overcome this disgust, some have proposed to flavor the milk with essence of peppermint or anise; others to add a little coffee, rum or whiskey; others still (as Harzen), broth. All these expedients may be tried; often they will succeed, oftener they will fail.

As for the applications of milk to therapeutics, they are numerous. As a diuretic, this alimentary medicament finds its place in diseases of the heart and dropsies. We apply its reconstituent and diuretic action to the treatment of the nephrites, catarrhal and interstitial. By reason of its rapidity of digestion, the little labor which it imposes on the stomach, the production of lactic acid which it determines, we are enabled with advantage to utilize milk diet in the treatment of simple ulcer of the stomach, the gastric catarrh of drunkards, and in gastritis generally. Its constipating properties render milk eminently serviceable in diarrhœa and in chronic dysentery. Lastly, its reconstituent properties render it applicable to the treatment of diathetic states, such as gout and tuberculosis. But do not forget that the sugar of milk contraindicates the use of this diet in diabetes, despite the contrary affirmations of Dongin, and that, in certain cases of dilatation of the stomach, the milk regimen, by reason of the very abundance ingested, augments the gastrectasia; moreover, in certain cases of too great acidity of the stomach, the milk is badly supported. These reservations do not retract from the real therapeutic value of milk, of which I shall hereafter have more to say.

In concluding what I have to say to-day about the employment of milk in medicine, I can but just allude to a very singular application of milk to cachetic and anæmic states. I refer to intra-venous injections of milk. Certain authorities, struck by the similarity which exists between milk and blood, have proposed to utilize the former in transfusion. Hodder was the first to practise intra-venous injections of milk in the case of three patients in collapse from cholera, and several physicians in the United States have followed his example, particularly Howe, of New York, Gaillard Thomas, Meldon, Robert McDonnell, William Pepper, and Brinton. Jennings also has made an able defence of the employment of transfusions of milk in the last stages of cholera, of typhoid fever, of pernicious anæmia, and as a *succedaneum* to the injection of blood in all cases where the latter cannot be readily obtained.

Medical authority has not favored this practice in France; and despite the favorable opinion of Brown-Sequard and Dupuis respecting these intra-venous injections, they have been regarded as extremely dangerous; and in support of this view the experiments have been cited of Laborde and Culcer, Moutard, Martins and Richet, and Miglior Ranza in Italy. These experimenters have shown that the globules of butter constitute fatty embolisms which determine mortal accidents, due to anæmia of the bulbus; moreover, they show that the the therapeutic value of these injections is very questionable. These experiments seem to me to have settled the question.

EGGS.

Eggs constitute a complete aliment for birds, though incomplete for man. If, in fact, the egg contains azotized substances, albumen, vitelline, and an extract of meat; if it contains a fatty matter, the oil of the yolk (a phosphorated oil); if also it contains salts it still lacks the requisite quantity of water to satisfy nutrition, so that if eggs are more nourishing than milk, (ten parts of milk representing one of egg), they are nevertheless inferior to milk as a complete food.

The different primordial elements of which I have spoken, are distributed in the egg in the following manner:

[7] Maurel. On the Treatment of Diarrhœa and Chronic Dysentery by Milk Diet and the mixed Regimen (Bale de Ther., 1881, t C p. 199.
[8] Reichmann. Experiments on the digestion of milk. (Zeitschrift für Klin. Med., 1885. ix).

Azotized matters	14 per cent.
Fatty matters	10 per cent.
Salts	2 per cent.

In an egg weighing fifty grammes, the shell represents six, the yolk eight, and the white thirty-six.

Eggs are rapidly digested, but the digestion is influenced especially by the degree of cooking. While a hard-boiled egg is indigestible, a rare egg is speedily digested and demands little labor on the part of the stomach.

The different albuminoid substances that compose the egg contain a certain quantity of sulphur, hence it often happens, and in cases where the gastric juice is deficient, that a putrid decomposition of eggs takes place in the stomach, giving rise to an eructation of sulphuretted hydrogen. This is what I have described under the name of *putrid dyspepsia*.

It seems demonstrated, that the egg albumen may pass out in the urine (see in this connection the experiments of Robinson and Semmola), thus constituting an alimentary albuminuria, analogous to alimentary glycosuria. Hence the white of egg is proscribed from the dietary of the albuminuric. I shall return to this subject when I come to speak of the dieteties of Bright's disease. But I ought to tell you here that recent experiments of Stokevis show that if an exclusive alimentation with raw eggs may determine the passage of albumen in the urine, it is easy enough to prevent this by cooking the eggs.

It has also been maintained that the albumen of egg possesses constipating properties, hence the white of egg has been recommended in the treatment of diarrhœa. I do not think there is much to support this view.

In pharmacy we make much use of eggs for emulsions; there is one which is in general use, and is described under the name of *lait de poule* (hen's milk), and which consists, you know, in emulsifying the yolks of two eggs in boiling water, and flavoring the whole with orange-flower water. I also recommend the preparation known under the name of *American cream*. You beat up the yolks of two eggs, add powdered sugar and flavor the whole with a little rum or brandy or sherry wine. This is a very strengthening nutrient mixture which is generally well supported.

Do not forget also that eggs poached in broth, or broth with the simple addition of the yolks of eggs forms a nutrient preparation which patients are likely to be fond of.

I have now finished the complete aliments, and propose to devote the next lecture to a subject much more extensive, the study of the complex aliments.

IODOFORM POISONING.[1]

BY ELBRIDGE G. CUTLER, M.D.

Most of the cases of poisoning by iodoform recorded have followed its application to wounds, but it has also resulted from internal administration (as is seen in the accompanying table, cases 56 and 57, by Oberlaender where 42.0 grammes were taken in eighty days and 5.0 grammes in seven days respectively), as well as when introduced into the vagina or rectum and when applied to the skin.

The symptoms observed have sprung from disturbances of the heart and brain more especially.

That the physical qualities of iodoform cannot be essentially different from iodine is seen from the fact that it contains 96.47 per cent. of iodine.

Animals. Experiments which have been made on animals with iodoform especially by Binz [2] Hoegyes [3] Moleschott [4] Moeller, and Hoepfl seem to bear out this belief. The symptoms which Binz and Moeller obtained after exhibiting large doses were hypnotic action, emaciation, fatty degeneration of the liver, heart, kidneys and lung epithelium. In the subcutaneous injection of iodoform the mucous membrane of the stomach was one of the first organs to be injured. Hoegyes observed besides the symptoms just mentioned, hæmorrhages into the lobes of the lungs. Death occurs with the appearances of general paralysis, according to Binz, special paralysis of the respiratory centre. Falkson [5] experimented by placing the iodoform in the peritoneal sac. He distinguished an acute and a chronic form of poisoning. In the acute the animal is languid, trembles a good deal, is sleepy, has no appetite, occasionally vomits, and has a disturbed gait. The somnolence increases to coma, respiration and the heart's action are quiet, the latter may be quickened, reflex excitation is retained in the coma, epileptic attacks frequently occur with marked opisthotanos. There is a decided loss in weight. An intermediate stage of apparently perfect health is seen between the operation and the beginning of toxic symptoms (in dogs), which shows that a certain cumulation of the poison occurs in the blood and tissue-fluids before these symptoms come on. This stage sometimes covers a period of several days.

In the chronic poisoning the preliminary stage of health lasts longer. The first symptoms are diminished appetite, with vomiting and increased thirst, then occur languor, indisposition to move, anger at being disturbed, nasal catarrh, dyspnœa, irregularity in the urinary secretion, albumen in the urine, emaciation, trembling of the muscles, coma, difficult respiration.

The result of his autopsies was similar to that of the above observers. He found that the iodoform might become encapsulated in the peritoneum just like any other foreign body, but its resorption was not thereby stopped. This same encapsulating was found to occur by Gussenbauer in some of his patients.

Human Subject. The toxic symptoms caused by iodoform in human subjects are very much the same as those obtained on experimentation with lower animals. A narcotic soporific action is observed and a considerable increase in the frequency of the pulse, 130 to 160 beats or more. These symptoms are not serious but sometimes very grave ones occur which may lead to a fatal issue. In some cases "aseptic fever," so-called, has been observed with a temperature of 103°, and death with a clear sensorium. More frequently, severe brain disturbances occur either with the picture of an acute meningitis or true mental disease which may be followed by death, even when the drug has been discarded. Autopsy in such cases has given fatty degeneration of internal organs, especially the liver. Sometimes very severe and lasting attacks of diarrhœa have been observed.

It has been found that in factories where iodine preparations are manufactured the employés suffer from acute, subacute, and chronic poisoning. The acute form is distinguished by severe irritative cough, headache, inflammation of the conjunctivæ and nasal mucous membrane, sometimes also by temporary loss of consciousness. In the subacute affection is comprehended protracted swelling of eyelids, flow of tears, severe frontal headache, frequent sneezing (iodine catarrh). Fever, elevation of temperature, increase of pulse seldom occur in these employés. More frequent than the above are cases of chronic poisoning, so-called iodism, a cachectic condition which develops as the result of frequent and lasting gastric catarrh.

Symptoms. The symptoms of poisoning by iodoform in patients show different degrees. Schede made out six degrees, Koenig divides cases into mild and severe, Nussbaum gives three as follows:

(1) The mildest form is that in which the symptoms disappear in a few days after removing the iodoform. They consist chiefly of iodoform taste and smell, patients cease eating, sleep little, are excited, angry, sometimes a little delirious and consider themselves sicker than they really are.

(2) The second degree is distinguished by complete loss of appetite which may increase to absolute refusal of food so that finally patients will not even swallow wine or beer; when they are persuaded to take food they complain that everything tastes like wood to them. The worst feature is the mental disturbance. There is melancholy and tearfulness, an excitability and despondency which is truly most painful for the patient and the friends. Morphia and chloral sometimes refuse to act. With open eyes patients frequently do not recognize those around them, suddenly spring from bed, will dress and attempt to get away without knowing why or where. They pick at the bed clothes, throw their arms about, are wholly inconsolable, believe that they will never recover and that they will surely become insane. This wretched condition may last for weeks in spite of leaving off the iodoform, it may make a pause and then come on again although the wounds treated with iodoform have long been healed; indeed this condition sometimes first occurs after healing (encapsuling, see case 19 in table). Finally refusal of food ceases, melancholy gives place to an animated appearance and patients recover.

(3) The third degree, on the other hand, shows itself two or three days after the application of iodoform, there is complete apathy, the patient wholly loses consciousness. From the beginning there is absolute refusal of food, the pulse is rapid and thread-like, respiration is sighing, there is sopor. Patients spring out of bed if they still have the power, cry out in words which are indistinguishable, and lisp or speak imperfectly. They lie for hours without reaction, then again they are unquiet. Morphia and chloral are often of no service. The temperature constantly sinks lower. The wild crying out and throwing about of the arms, picking and tearing at the bed-clothes and dressings, permit us to suppose that patients have most unpleasant sensations. All stimulating means, camphor injections, ether, atropine, strychina and so forth prove to be wholly fruitless. The removal of all the iodoform is of just as little use. Patients die with the appearance of pronounced collapse after they have been for hours and days even cold and pulseless with stertorous breathing.

These groups include most of the prominent symptoms, individual cases present others which may be mentioned.

Long continued headache is frequent.

Rise of temperature is not unfrequently seen, though severe even fatal cases run their course without it; 102° is seldom exceeded.

The pulse is almost always increased in frequency, usually as the case progresses towards a fatal issue it becomes small, easily compressible and weak. It ranges from 110 to 180 or a number which cannot be counted.

The respirations are frequently suspirious, or superficial and rapid.

The tongue may have a brownish coat.

Restlessness and delirium are very frequent symptoms. Involuntary discharges are not rare.

Emaciation is marked usually, especially in the chronic cases and where it is progressive a fatal issue is to be apprehended.

Pallor and a feeling of faintness with a good pulse are not so very rare.

Feeling of weakness, hebetude and sleeplessness accompany the milder cases usually.

Nausea, vomiting and anorexia are extremely frequent.

Papulous and simple erythema of the whole body has been seen; it usually has disappeared rapidly on leaving off the iodoform.

The symptoms are most striking and severe at night usually.

Chemical changes. Hoegyes considers that iodoform dissolves in the fatty matters with which it comes in contact, from this solution iodine becomes free and forms with the albumen present iodine albumen which is resorbed. According to Binz and Moeller it is dissolved by the fat, iodine is set free which is changed by the alkali present, into iodides and iodates which again circulate in the blood and act on the ganglion cells of the brain and finally appear in the urine and other secretions as iodide of soda and other iodine organic compounds. They deny the occurrence of the intermediate stage claimed by Hoegyes of iodine albumen.

Behring, who experimented on rabbits, thinks that

iodoform acts by abstracting alkali from the organism, that in sufficient doses it may cause the death of the animal by this action, and that one may by a proper exhibition of alkali establish a remarkable tolerance of iodoform.

Ætiology. It is difficult to explain why the poisoning occurs. Various views are entertained on this point. The manufacturers have been blamed, the article being at first expensive and now cheap, it has been suggested that the iodoform might perhaps be impure. That this is not the case may be inferred from the fact that the best and worst results have followed the use of the drug from the same parcel. Others believe the cause to lie in the variable power of absorption of the tissues and consider that it has an especially injurious action when it comes in contact with much fat because it becomes dissolved thereby. If this assumption were correct we should expect to see very fat persons more susceptible to the drug than others, which has not thus far been observed to be the case. Others again, blame the age of the individual, that is advanced age. Young people are said to bear it well, cases of poisoning are less severe with them because they can eliminate it better, their organs of elimination being more apt to be sound at the start. It is certain that of the recorded cases fewer deaths have occurred under the age of fifty than above it. Idiosycrasy is a sufficient cause for many. Ludwig thinks that in the circulation of iodoform through the body besides the giving off of iodine there is probably some other organic combination formed which causes the toxic action. Nussbaum [6] believes that probably the concurrence of many conditions causes a liability to poisoning. He speaks especially of a large fatty wound capable of resorption, degenerated heart muscle and diseased kidneys, and recognizes also in a sick enfeebled organism the most dangerous disposition to iodoform poisoning. Mosetig finally regards the simultaneous application of iodoform and carbolic acid as the chief cause. He always used pure iodoform treatment himself. He washes the wound with clean water, then strews the iodoform powder on it and over it lays charpie free from fat and gutta-percha paper. The carbolic acid, according to him, causes nephritic irritation and that is said to hinder the elimination from the body and so cause poisoning. This opinion has a great deal of probability in its favor, first, because Mosetig in spite of his very extensive use of the treatment (3,000 hospital and 4,000 ambulatory patients), has observed no poisoning at all, and second, because in many of the cases recorded in the above table other disinfectants are stated to have been used at the same time. On the other hand the number of cases where no mention of other disinfectants is made, is very large and there are also many where none such could have been used. We are forced therefore, to the conclusion that the cause is yet to be proved.

Bum arrives at the following conclusions:

(1) Iodoform has a poisonous action when the iodine freed in the organism does not become perfectly combined.

(2) This poisoning will happen where the quantity of iodoform introduced is 1, over large, 2, and in qualitative and quantitative changes of the blood. It is surest to occur where these two forces work together.

(3) The use at once or in short intervals of very large quantities of iodoform, especially in anæmic, very young and old individuals is to be avoided.

(4) The iodoform dressing is to be changed as seldom as possible in order to avoid a cumulative action, (and at the same time the iodoform is not to be removed the wound washed and fresh powder or other form applied, as a surface the best suited for absorption is left.)

(5) The iodoform in the wound must never be exposed to a strong pressure as it aids absorption; the dressing is therefore never to be applied tightly.

Absorption. With regard to the absorption of iodoform Zeller [7] found that the solubility of iodoform in water was the same as in blood-serum, that is, 0,212 grammes to 1,000 grammes water. Resorption from the stomach was very slow (shown by determining the quantity of iodine eliminated in the urine), that from the peritoneal surface very rapid, and that from the surface of wounds could not be reckoned. Falkson found that even dry crystalline iodoform was absorbed through the intact skin. He made four experiments on different individuals by strewing crystals of iodoform on the forearm and covering it with dry charpie free from fat and gutta-percha paper. After twenty-four to forty-eight hours the urine gave the iodine reaction distinctly. The arm on removing the bandage was always perfectly dry. General testimony seems to prove that a granulating surface will absorb it more readily than a fresh wound, a serous membrane quicker than a muscle-wound, a freshly-sawed bony surface easier than a sequester-capsule, a serous surface in normal condition better than a thickened inflamed one. It is absorbed very readily from the vagina. When applied to a wound by the finger or rubbed in, absorption seems to be almost certain.

Detection in Urine. If the iodine reaction is not obtained in all cases in the urine where iodoform is employed it certainly is obtained in all degrees of poisoning. In some severe cases there is albumen and perhaps casts in addition.

(1) To detect iodoform or rather iodine in the urine, the compound is to be first decomposed by fuming nitric acid and dilute sulphuric acid, then a little starch paste and a few drops of bisulphide of carbon are to be added, whereupon a beautiful blue color occurs. On shaking it about, a small portion of the iodine is dissolved by the bisulphide of carbon and a dark-blue ring of iodide of starch is formed on the layer of bisulphide of carbon.

(2) A second though less reliable method is as follows: After starch paste and dilute nitric acid have been added to the urine a few drops of fuming nitric acid are added, when a blue color occurs which on heating disappears and returns again on cooling.

(3) By a third method, after sulphuric acid and fuming nitric acid have been added the fluid is shaken with chloroform. There occurs through solution of the iodine in the chloroform a violet color.

(4) Sometimes the iodine is in such combination that the above reagents do not free it, chlorine water may then be added for this purpose, as I learn from Professor Hills, or the urine may have to be incinerated and then tested (Harnack).

Pathological appearances are not constant.

Fatty degeneration of the heart muscle, cloudy swelling of the renal tubular epithelium and fatty de-

[6] Werth und Gefahr der Antiseptica, Vortrag in der Sitzung des Aerztlichen Vereins zu Muenchen am 12 April, 1882.

[7] Versuche ueber die Resorption des Iodoform. Congress of German Society of Surgery in Berlin, June, 1882.

generation of the liver have been reported not unfrequently; sometimes gastritis has been seen. Croupous pneumonia has been observed by Aschenbrandt in lower animals after inhalations and "pneumonic symptoms," by Koenig, Case 22 (no account of autopsy). In this latter case and in Cases 24 and 32 of the table the suspicion is well founded, I think, that the appearances were probably due to inspiration of foreign matter from the wound or of particles of food. Œdema of the lung has been several times observed. Sometimes there has been œdema of the meninges or brain. Harnack found that certain organs of the body, namely, the brain, contained disproportionately more iodine than others, as the liver and kidneys, and curiously enough, this was found far more abundantly in the cerebellum.

General Remarks. With regard to the age of the individual the table shows that of seventy-seven cases of poisoning, twenty-six were under forty years, about one third, and that of the fatal cases, twenty-nine in number, all but two were under forty. A larger number of cases might materially alter these figures.

There seems to be no maximum dose of safety from symptoms; one gramme has given rise to grave consequences and even from a minute amount as in Bermann's case, number 35, in the table, unpleasant results have followed. On the other hand, large amounts 100 to 200 grammes or more have proved harmless.

The smaller the amount of surface covered by iodoform, and the less natural cavities of the body are exposed to its action, or freshly-cut bones, the better is the chance of immunity. Iodoform should never be smeared on or rubbed in, either as powder or salve. No accompanying disinfectant, as carbolic acid or corrosive sublimate, should be used.

Prognosis. In youthful persons a quickening of the pulse, 130 to 140 beats in the minute, may last for a long time without any other disturbance following, but if in adults or elderly people free from fever, a permanent and considerable frequency and diminution in strength of the pulse occurs, danger is at hand. If the mental condition gets worse and coma comes on with collapse the prognosis is grave. Emaciation if progressive is dangerous, but where it remains stationary or slightly diminishes the prognosis is favorable.

Treatment. It has been theoretically proposed (Harnack) to give compounds of the alkalies with vegetable acids internally at the first appearance of the symptoms of poisoning, as acetate of potash, and so forth. The object being to furnish the system with abundance of alkali which may combine with any free iodine which may be present. For this purpose the potash are better than the soda compounds, as poisoning has followed the use of the latter.

This course was pursued by Behring in Case 64. If this treatment does not prove beneficial, transfusion of an alkaline common salt solution is suggested, as was successfully accomplished by Kocher, Case 59. Harnack further suggests that the iodoform be washed off the wound with an alkaline carbonate solution, and then with luke-warm water, and that lastly magnesia usta be powdered on.

Conclusions. From what has preceded, the following conclusions seem warrantable:

(1) Fresh wounds or unhealthy or tuberculous surfaces are the only ones fitted for the application of iodoform.

(2) Only a thin layer or small amount of iodoform is to be applied.

(3) When granulations appear healthy, iodoform should be omitted and some other non-poisonous substance substituted.

(4) At the first symptom of poisoning, or coincidently with the original use of it, compounds of the alkalies and vegetable acids are to be given by the mouth at frequent intervals, as acetate of potash. If severe symptoms supervene, transfusion with common salt solution is to be resorted to, and the wound is to be washed free from iodoform with pure water and an alkaline carbonate solution and afterward powdered magnesia is to be dusted on.

ABUSE OF MEDICAL CHARITY. — A REMEDY APPLIED IN 3000 CASES OF OUT-DOOR PATIENTS: RESULTS.[1]

BY FREDERICK F. DOGGETT, A.B., M.D.,
District Physician to the Boston Dispensary.

AT the present time when "a little less than one-fourth"[2] of the inhabitants of Boston is receiving medical treatment free of charge, it is certainly of great moment to the physicians of Boston to learn to what extent their charity is being abused, and if possible to find some remedy to correct such abuse.

It is hardly necessary to say a word as to the mere existence of such abuse, as it would be almost impossible to find a physician, who has had even a limited experience with charity cases, who would deny it. With such a physician it is perhaps his weekly or even daily experience to treat gratuitously certain persons who live in comfortable homes, well furnished, are themselves well clad, not only able to procure all the necessities of life, but even many of the luxuries. Many persons in such circumstances, in considering their expenditures, seem to make no provision for sickness, but as a matter of course look upon medical treatment as a blessing as free to them as air or sunshine, and so appropriate what may be left over from the cost of necessities of life to an evening at the theatre or to some other gratification equally out of place under the circumstances.

To those who have not had experience with charity cases, does it seem probable that all the ninety thousand and more persons in Boston applying for free medical treatment are objects of medical charity? Luckily, we have a standard of numerical comparison whereby we can, reasoning from analogy, raise the question above probability. In New York City the experiment has lately been tried of investigating the circumstances of each doubtful case, *seriatim*, as they applied at the New York Dispensary. The number of cases investigated[3] was 845; of this number, 504 were deserving; 235 were not; 38 were doubtful, and 68 could not be found. Thus 59.6 per cent. were deserving.

Dr. A. Siebert[4] of the German Dispensary, reports that out of 434 cases investigated, 107 gave wrong addresses; 187 were fully able to pay; 42 were able to pay small fees; 75 were unable to pay, while 23 gave no answer. In another series,[5] investigated for the managers of this dispensary by the Charity Organization Society, from January to March, inclusive, 1884, out of 192 cases, 64 were able to pay, 65 not able, while 63 gave wrong addresses.

In another New York charitable institution, in a series[6] of 79 investigated, 24 were able to pay and 27 gave wrong addresses. And finally, in another series of 400 cases, one-third was unworthy and one-third had given wrong addresses. As a result of these investigations, it was found that something over 50 per cent. of the cases were unworthy of medical charity. In the light of these figures, is it not reasonable to suppose that at least a large minority of such cases are to be found in Boston? Further evidence on this point will be adduced from the writer's figures as given later in this paper, which would go to prove that at least 23 per cent. of all cases applying in Boston are unworthy of medical charity. Much of the same results have been obtained in similar investigations in Philadelphia.

And when we consider that in London and New York, more than one-fourth of the inhabitants are treated free of charge; in Philadelphia, one-fifth; while in Liverpool 298,260 persons out of a population of 579,724,[7] or more than one-half, are so treated, — one can realize the extent to which the abuse has gone.

It is not proposed in this article to consider the causes which have produced this state of affairs, wherein so large a proportion of the inhabitants of large cities have got into the fashion of seeking medical charity. Nor is it necessary to consider in this place the motives which induce medical men to give so much of their services. However widely writers on the subject have differed on these two questions, there seems to be much unanimity in the opinion that promiscuous medical charity is alike demoralizing to the recipient, and detrimental at least to the income of practitioners taken as a body.

Scarcely a month passes in which the *London Lancet* or *British Medical Journal* fails to contain some complaint of the absorption of private patients into Provident Associations or free hospitals and dispensaries. In an editorial in the *London Lancet*[8] on a paper by Mr. C. J. Radley on "The best plan for establishing Provident Dispensaries in due relation to hospitals," there will be found abundance of such complaint; also in another editorial[9] on a proposition to disfranchise persons receiving medical charity. New York and Philadelphia journals have of late mirrored much the same state of affairs in those cities, especially in the former. Dr. W. L. Carr[10] has written on the impoverishment of the young physician through abuse of medical charity. While "Caritas Vera"[11] complains that in going a not very long distance to visit a certain patient, he must pass by no less than four free dispensaries. He suggests that if patients were questioned more thoroughly by dispensary physicians there would be less abuse.

The abuse of medical charity having for some time been admitted, and the wide-spread evils therefrom noted, attempts have naturally been made to remedy the trouble. The two principal schemes which have been tried are the Provident Societies, principally in Europe, and the Charity Organization Society in America. In the London Provident Society — the earliest type of them all — the person seeking medical aid may be elevated from the position of a charity patient to the dignity of a pay patient, by paying the sum of sixpence per month; of ten-pence for husband and wife, and two-pence for children under fourteen years of age. The scheme does not seem to thrive on American soil, for some reason. In England, one would judge from editorials and communications in the British journals, that on the one hand the scheme diminished the receipts of the physician while adding to his labors; while many apparently respectable persons who would scorn to accept charity as such, have satisfied their scruples and avoided the physician's bill by joining a Provident Dispensary. In this way the

[11] Idem, Feb. 7, 1885, p. 168.

abuse of medical charity has not been corrected but has taken a more respectable form, in which guise the abuse is more difficult to meet.

In case of the Charity Organization Society, it is proposed that the various charities of the city, instead of working at cross purposes — as, for example, by assisting a family previously found unworthy of assistance by a neighboring charity — shall have a system of intercommunication, and shall assist only those cases which are found worthy after examination of their circumstances. Thus the register of the New York Charity Organization Society contains the names of 98,000 families who have applied for medical relief, together with their standard of worthiness or the opposite.

Of late many such alliances have been established in European cities as well as in no less than forty cities and towns in this country. It is hardly necessary to say that the investigation bears on general relief as well as medical. In the writer's opinion, this scheme is calculated to do great good. For instance, if all the charitable institutions in Boston should agree to treat no case that did not bring a card from the Associated Charities, say, endorsing the person's worthiness after investigation, how completely would the abuse of medical charity be stopped! But that ideal time has not yet arrived.

If it were possible for each dispensary and hospital to contain a register of the thousands of families in Boston unworthy of medical charity, it would apparently not be difficult, nor would it take too much of the physician's time, to decide which cases to reject. In the absence of such information, at present it is possible to learn through a card of the Associated Charities the charity status of any family, where it is possible to look it up. This might work reasonably well in cases of no urgency, as with most of those coming to the consulting rooms of hospitals and dispensaries. Of course, treatment would usually have to be deferred for twenty-four hours. But in regard to cases sick in bed such as the district physician attends, prompt treatment is demanded by the nature of the case, and time could not be allowed for investigation. In the light of these suggestions, it must be admitted that the scheme would be cumbrous as applied to the district physician's work.

During the early months of his district dispensary practice — October to December, 1882 — it became evident to the writer, judging from the surroundings of many of the patients — as from the rents paid, the furnishing of their houses, and the amount of their wages when discoverable — that many were able to pay their physician's bills.

The position of affairs cannot be better illustrated than by relating two or three of the more glaring cases.

He was called to treat a sick child in a family occupying a well-furnished suite of rooms. On inquiring as to the apparent prosperity of the family, the mother declared that they had seen better days, but that her husband was then sick in the hospital with an incurable disease, and that the rest of the family was living on money loaned on the furniture. Some time after, it was learned accidentally through another family living in the same block, that in reality the husband was well and attending to his busines; he being the junior partner in a liquor firm which owns two establishments, not far from the lower end of Broadway, South Boston.

In another case where the writer's suspicions were aroused, the mother declared that her husband earned but six dollars a week as a barber working on short time, and with several children they were very poor. The husband was afterwards discovered to be the proprietor of a barber's shop on Broadway, and there was business enough to compel him to hire two assistants. He was amply able to pay his physician's bill.

In still another case, after having treated a woman on several occasions it was accidentally learned that her husband owned the house in which lived another family besides their own; that he further owned two horses and carts and was doing a retail coal business.

It is perhaps hardly worth while mentioning the family who explained that the reason they could pay no physician's bill, for the time being, was, that they had to set apart a certain sum each month, to meet a bill on a comparatively expensive set of furniture they had lately purchased on the instalment plan.

And finally, may be noted the case of the lady — previously a private patient of the writer's — who clad in her third-best dress, probably for the occasion, unwittingly stepped into his presence for treatment at the woman's room at the Dispensary.

It is only fair to say, that aggravated cases like the above were only encountered while the writer was yet new to the district, and before he began to question as to the circumstances of the patients.

(To be continued.)

RECENT PROGRESS IN OPHTHALMOLOGY.

BY O. F. WADSWORTH, M.D., AND MYLES STANDISH, M.D.

ANATOMY OF THE HUMAN IRIS.

FUCHS[1] has made a study of the iris with particular regard to its surfaces. He made sections of the specimens so studied to explain what was seen on the surface. He found brown irides the most favorable, and selected those having a medium pupillary opening. (3 to 4 mm.)

The anterior surface of the iris. A circle divides this surface of the iris into two zones of unequal width, the pupillary and the ciliary zones.

The pupillary zone has a breadth of about 1 mm., and is crossed by a number of ridges which extend from the circle to the pupil's edge. In the depressions between these ridges a fine brown network can be seen with a high power.

The ciliary zone which constitutes the greater portion of the iris, is partially if not entirely hidden behind the sclera in the living eye. This contains a plicate zone made up by a series of nearly concentric furrows, from one to seven in number, and a marginal zone, commencing at the outermost furrow of the plicate zone, and which is distinguished by a number of apertures in its surface giving it a sieve-like appearance. The anterior surface of the iris is covered with endothelium, immediately beneath which the iris-stroma is much richer in cells than elsewhere; this layer is the anterior limiting membrane. The fibres are extremely fine and run perpendicularly to the surface. The anterior limiting membrane is thickest in the flat portion of the ciliary zone and on the prominent ridges of the plicate portion. The cells of this layer contain pigment, and upon its amount depends the color of the iris. The crypts, the apertures spoken

[1] Archiv für Ophthalmologie, Bd. xxxi, Abth, iii.

of above, lie mostly to the outer side of the small circle, but also somewhat on the inner side. The crypt is not a blind sack but a lymph space opening into the iris. The anterior limiting membrane bends over into the mouth of the crypt, and becoming thinner as it extends inwards is finally lost at some distance from the surface. The vascular layer of the iris occupies the space between the anterior and posterior limiting membranes. This space is made up of the vessels and their adventitia, exceedingly fine fibrillæ of connecting tissue, and some branching cells. It is an open and sponge-like tissue, the central portion about the larger vessels being especially open, having large spaces, freely connecting with each other. We have, therefore, in the iris, a system of great slit-shaped channels, in the midst of which the vessels lie, and these canals connect the meshes of the ligamentum pectinatum with the anterior chamber by means of the open mouths of the crypts.

The posterior surface of the iris is covered with radiating folds, in addition to which there are deep concentric furrows parallel with the pupillary margin.

The pigment on the posterior surface is divided into two layers, the outermost layer is much the thicker and consists of many layers of cells, and is folded on itself, as described above, the inner layer is, however, perfectly flat, and consists of flat cells intimately adherent to the posterior limiting membrane, and these layers can move one upon the other. The posterior limiting membrane consists of fine radiating fibrillæ which have no neuclei, and so are certainly not muscle. This membrane is the only layer not thrown into folds by the dilitation of the pupil, and consequently must be the active agency in dilating the pupil. As the result of his investigations, Fuchs denies the existence of a dilator muscle in the iris of man.

When the pupil contracts, all of the tissues are stretched in a radial direction, the vessels are straightened, the circular furrows are made shallower, the small circle becomes more marked, the crypts in its neighborhood are drawn out into thin slits and nearly closed. On the posterior surface the radial folds become more prominent and the circular ones shallower. Sections show that the thickness of the iris lessened during contraction. When the pupil dilates the changes are the converse of those seen in contraction. The vessels become strongly convoluted, the circular furrows deep, the mouths of the crypts become more circular or, in extreme dilitation, become slits transversely to a radius of the iris. The thickening of the iris is chiefly in the pupillary zone. During the contraction of the pupil the apertures in the pupillary zone become smaller, and those of the periphery larger, and the opposite is true in dilitation. It is probably through these channels that the iris absorbs blood and pus from the anterior chamber. The movements of the iris probably aid in the propulsion of fluids in these canals.

This anatomical arrangement has probably some bearing on the action of mydriatics and myotics on intraocular pressure.

INNERVATION OF THE IRIS.

Kowalenski[3] has published an elaborate historical review of the investigations of the nerve centers controlling the dilitation of the pupils, followed by a long series of investigations of his own, from which he draws the following conclusions:

(1) The hypothesis of Schiff and Salkowski, as to the course of the nerve fibres dilating the pupils, from the intra-cranial center through the lateral portion of the cervical portion of the spinal cord, and through the cervical portion of the sympathetic nerve to the eye: also,

(2) The hypothesis of Budge of the existence of an autonomous centre in the spinal cord for fibres dilating the pupil, do not agree with the facts.

(3) The autonomous centre of the fibres dilating the pupil lies in the cranial cavity and can be excited by reflex irritation.

(4) Inter-central exciting fibres pass from this centre to the cellular origin of the dilators of the pupils in two directions, through the cerebrum and through the spinal cord.

(5) The fibres passing through the spinal cord seem to take their course through the lateral columns; each lateral column contains exciting fibres for both sides.

(6) The dilators of the pupils coming from the spinal cord do not all pass to the eye through the cervical portion of the sympathetic nerve, some taking another course. (vertebral nerve?)

(7) The lateral columns are the main channels for transmitting the irritation from the sciatic nerves to the cerebrel centre of the dilators of the pupils, each column containing fibres of both sciatic nerves in the cervical portion of the spinal cord. Each one is capable of transmitting reflex irritation to the dilators of the pupils of both sides.

(8) That the pneumogastric, hypoglossus, lingual, and intra-orbital nerves also dilate the pupil by reflex irritation, as well as the sensory nerves.

(9) The cerebral centre of the dilators of the pupils can also be excited by checking the supply of arterial blood to the brain (by compressing the carotids), and by suppressing respiration.

Schweiger[3] notes that after the complete denudation of the posterior circumference of the globe (resection of considerable sections of the ciliary and optic nerves), if the operation be performed in a case with normal iris the effect is mydriasis ad maximum, so that atrophia has no further influence. Eserine, however, will produce well-marked myosis, except in cases in which the drug could not have produced any effect before the operation, as, for instance, in glaucomatous mydriasis. From this reaction to the influence of eserine no inference can be drawn as to the regeneration of the motor-nerve fibres; besides, no contraction of the pupil can be produced by the entrance of light into the other eye.

ABSENCE OF PUPILLARY REFLEX.

Uhthoff[4] has published a very interesting tabulation of cases in which there was absence of pupillary reflex (Argyll Robertson pupil). He commences with a description of his method of examination. He prefers a dark room and concentrates the light from a gas jet upon the pupil by means of a convex lens. He warns observers against overlooking slight reactions in small pupils, and of the dangers of mistaking movements of the globe, and the reaction of the pupil to efforts of accommodation for the reaction to light. He objects strenuously to the method sometimes employed of

[3] Kowalensky. Investigations on the Innervation of the Pupil. Kasan, 1885. Archives of Ophthalmology, Vol. xiv, No. 4.

[3] Archives of Ophthalmology, Vol. xiv, Nos. 2-3, p. 231.

[4] Berliner, Klin. Wochensch, 1886, Nos. 3-4.

causing the patient to close his lids for a few moments and then suddenly opening them. He first reviews the results of the examination of four thousand cases of mental disease by Mœli, Thomsen, Siemerling. In these four thousand cases, absence of pupillary reflex occurred in four hundred and ninety-two individuals, of which number four hundred and twenty-one were general paralytics; twenty-one had tabes; eleven, senile dementia; eleven, chronic alcoholism; nine, syphilis; six, focal lesions; three, head injuries, without other cerebral symptoms; and ten cases had either mental alienation or epilepsy. The fact that these four thousand cases were all cases suffering from mental disease accounts, of course, for the comparatively small number of tabetics. Old age, while very often producing small pupils, does not produce an absence of the pupillary reflex. The symptoms occurred in more than half the cases of general paralysis. Many of the cases were under observation for long periods of time. Uhthorff himself made three distinct sets of observations.

First, he examined several hundred healthy persons and did not find the pupillary reflex absent in a single case.

Second, he examined a large number of cases in various hospitals, and only found the condition present in cases that would naturally come to a clinic for nervous diseases.

Thirdly, he examined 550 patients in Westphal's clinic for nervous diseases, and 12,000 cases attending Schœler's clinic of diseases of the eye. Among the 12,550 cases in Schœler's and Westphal's clinics, absence of pupillary reflex occurred 136 times, excluding cases of ophthalmoplegia interna.

Of these 136 cases: I. 92 had tabes. Included in these 92 cases credited to tabes, are six cases in which the diagnosis was not absolutely certain, 4 in which the light reaction was not absolutely wanting, 29 in which atrophy optici existed, 15 who had ocular paralysis, 5 who had paralysis of accommodation in one eye, and 12 in which there was marked difference in the size of the pupils.

II. Twelve had general paralysis, of this number 4 had atrophy optici.

III. Eleven had syphilis, including cases of cerebral syphilis.

IV. Eight had other cerebral diseases, injuries to the head 2, cerebral tumor 2, hydrocephalus 1, post-neuritic atrophy 1, hemiplegia 1, pachymeningitis 1.

V. Two had multiple neuritis.

VI. Two had railway spine.

VII. In two cases the phenomenon was congenital, but in both cases there was only a rudimentary development of the iris.

VIII. One case was congenitally imbecile, but this patient had also retinitis pigmentosa, with a very large amount of concentric diminution of the field of vision.

IX. One case had an aneurism of the innominate artery, the phenomenon in this case our author considers as probably due to pressure on the sympathetic nerve.

X. One case had a history of the abuse of tobacco.

XI. One case had a head injury but had also a history of the abuse of alcohol.

XII. One case had right-sided hemianæsthesia.

XIII. One case had hystero-epilepsy.

XIV. In 3 cases the cause was unknown.

There were 30 cases, in addition to those above enumerated in which there was loss of the power of accommodation, as well as of the pupillary reflex (ophthalmoplegia interna).

These cases are classified as follows:

(1) Syphilis 8 cases, 6 unilateral and 2 bilateral.

(2) Tabes 3 cases, 1 bilateral, 3 unilateral.

(3) General paralysis, 1 bilateral, 1 unilateral.

(4) Trauma 2 cases, both bilateral.

(5) Chill (exquisite Erkältung) 1 case, unilateral.

(6) Commencing tubercular meningitis (?) 1 case, bilateral.

(7) Cerebral tumor (?) 1 case.

(8) Cause unknown 12 cases, 7 bilateral, 5 unilateral.

Syphilis is much the most common cause of this affection, and the impairment of functions is almost always unilateral, in one of the above cases in which it was bilateral, the second eye was affected years after the first. When a history of the date of the infection could be obtained, it was, as a rule, seven or eight years before the appearance of the ophthalmic symptoms. The cases in which the cause was unknown, occurred chiefly in young people and was transient in its duration.

CATARACT IN GLASS-WORKERS.

In the course of two years, Meyhöfer[5] observed four cases of cataract in glass-workers under thirty years of age, healthy in all other respects. This led him to the examination of five hundred glass-workers, all of whom were engaged in glass-blowing or other work which kept them in the immediate neighborhood of the open furnaces. Fifty-nine presented cortical opacities of the lens, forty-two of these being under forty years of age. The left eye was much the most frequently affected, this side of the face being the one generally more turned toward the fire. In none of them could be discovered any disease of the fundus which could be regarded as cause, or as complication, of the cataract. The only general disease hitherto recognized as a cause of the early formation of cataract is diabetes. But this, according to the testimony of physicians practising among glass-workers, is not specially prevalent among them, and in the eight cases whose urine Meyhöfer was able to examine, he found no sugar. The author is of opinion that the cause of the cataract is the intense radiant heat from the open furnaces, and the consequent profuse sweating to which the men are subjected. The left side being especially exposed to the direct heat, explains the greater prevalence of cataract in the left eye.

INTRA-CAPSULAR IRRIGATION IN CATARACT EXTRACTION.

At the Ophthalmological Society of the United Kingdom, in October, 1885, McKeown[6] read a paper on this subject. His method consisted essentially in the substitution, in the operation of extraction, of washing out of the cortex for pressing, rubbing, and scooping out. He made a small, flap section of the cornea, and iridectomy. After lacerating the capsule freely and expelling the lens, if any cortex were left behind, he introduced a scoop-syringe well within the capsule and gently injected distilled water of the temperature of about 100° F., making gentle motion at the same time with the scoop, to facilitate removal. He had used the scoop-syringe, in all, thirty-nine times. In

[5] Klinische Monatsbl. für Augenheilkunde, February, 1886.

[6] Ophthalmic Review, November, 1885.

one case only was there irido-choroiditis with complete closure of pupil; in one, insidious iritis, beginning after discharge of the patient from the hospital; in a syphilitic subject, severe iritis, arrested by treatment. In no case suppuration of eye or cornea; in none escape of vitreous from use of the syringe. In a few cases, some iritic adhesions, causing no pain or diminution of vision. In twelve cases the cataracts were unripe, and in several the cortex very sticky. There was only one inflammation in the last thirty cases, and that in the syphilitic subject referred to. There were two cautions to observe: first, after iridectomy, to get the blood out of the anterior chamber as quickly as possible; secondly, to be careful to introduce the scoop within the capsule. The operations were all done without chloroform, and some of the patients were restless. The conclusions which he thought he might draw from his own experience were: (1) that the judicious injection of water within the capsule of the lens was innocuous; (2) that it was not liable to cause loss of vitreous; (3) that it was advantageous, both in ripe and unripe cataracts; (4) that it shortened the average duration of cataract operations; (5) that it was a most efficient means of cleaning the wound.

Wicherkiewicz [7] states he had, for years, the idea that unripe cataracts might be completely removed at one sitting by division of the anterior capsule and washing out. As narcosis seemed necessary for such an operation, however, and he always operated on cataracts without an anæsthetic, it was only after the introduction of cocaine that he employed the method. To obtain more constant and steady irrigation than by a syringe, he had made a glass globe with two spouts, the one short, to be closed by the finger of the operator till the proper moment, the other long, curved, tapering, and terminated by a silver canula with small opening at its tip. After opening the lens capsule and pressing out so much of the lens as comes readily, the canula is introduced, the finger removed from the larger spout, and the fluid allowed to flow into the eye until the lens substance is thoroughly removed, then the canula withdrawn while the stream is still flowing. The fluid used has been a one or two per cent. solution of boracic acid, boiled, and cooled to 30° C. Wicherkiewicz had operated in eighteen cases, but does not give the statistics, because the number is too small to draw safe conclusions from, but is convinced that the method is of advantage. He has employed it for unripe senile, traumatic, and zonular cataracts. In one case, carbolic-acid solution was introduced by mistake (strength not given), and although it washed out the lens substance, it caused considerable pain and inflammation, but the case eventually did well.

TRANSPLANTATION OF THE CORNEA.

Von Hippel [8] showed a patient at the Medical Society of Giessen, in whom a better result had been obtained than in any case hitherto reported. Governed by the supposition that the opacity which had supervened in all previous cases of corneal transplantation was possibly caused, in part, by the rapid development of vascularization from the edges of the wound, in part by the action of the aqueous humor on the corneal tissue, he operated in a manner designed to exclude the influence of these factors. The patient had a central, non-adherent leucoma of glaring white color, which did not extend through the whole thickness of the cornea, but left the membrane of Descemet free. To the outer and inner side of the leucoma there was diffuse opacity of the anterior layers of the cornea, in which, from either side, a fine vessel ran toward the centre. Fingers could be counted at two metres with excentric fixation. The leucoma was circumscribed with a trephine, and the corneal opacity removed, layer by layer, with forceps and knife, close down to Descemet's membrane; then, with the same trephine, a piece the whole thickness of the cornea was removed from a rabbit, and placed in the cavity left in the human eye. Under an iodoform bandage, union occurred without any reaction, without vascularization or swelling of the transplanted piece, and up to the time the patient was shown, four weeks after the operation, the graft had maintained its normal transparency. Vision, with central fixation, was then 20-200, and there was a great improvement in the appearance. A foot-note states that four months later, five months after the operation, vision was still unchanged.

IODOL IN DISEASE OF THE EYE.

Glässner [9] has employed in various diseases of the eye, iodol, a substance which has been proposed as a substitute for iodoform. It is said to lack the poisonous properties of iodoform, and possesses the further advantage that it is almost odorless. The preparation used came from Kalle & Co., in Biebrich, and had the form of a light brown powder. Glässner applied it both as a fine powder, and also with vaseline as a one-third per cent. salve. In ulcers of the cornea and hypopion-keratitis, powdered iodol acted as well as iodoform, although, at first, the evidences of irritation were somewhat greater. In phlyctenular and trachomatous panuses, application of a two per cent. salve rendered good service; it also caused rapid absorption of superficial corneal opacities. In a case of obstinate iritis serosa, with marked opacities on the posterior surface of the cornea, which had continued in the same condition nearly four weeks, application and rubbing in of iodol salve brought about clearing and improvement of sight in a few days. No beneficial effects were observed with phlyctenulæ of the conjunctiva, either from the powder or the salve. In the later stages of granulations, iodol salve seemed to hasten the healing, and blepharitis healed promptly under treatment by it.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M.D., SECRETARY.

May 10th, 1886, the President, Dr. F. W. Draper, in the Chair.

URETHAN IN CHOREA.

Dr. Abbot referred to the case of chorea which he had spoken of at the previous meeting, and said he had heard from the father of the child that it was rapidly recovering at the present time. Urethan had been used merely as a hypnotic, with the most satisfactory result. The general course of treatment in the case he had not learned.

VANILLA POISONING.

DR. B. F. DAVENPORT said that he wished to call the attention of the Society to the possibility of poisoning by the use of vanilla extract as a flavoring. Instances of this kind have been reported in the *Pharmaceutical Journal* of London, for 1874, and mention made of them by Dr. Abbot in the BOSTON MEDICAL AND SURGICAL JOURNAL for November 8, 1883.

Within about six months, he had himself met with three cases of it. In the first case, a family of some six persons were taken suddenly sick with severe symptoms of gastro-entroritis, and that in relative degree, as they had severally partaken of some vanilla ice cream at the preceding meal. In the second case, at a Sunday School festival, where vanilla ice cream had been served, some thirty persons who had taken it were likewise affected, but no one was taken ill who had not partaken of this particular cream. In the third case, which occurred yesterday, all the members of three families, who had eaten of a certain baking of cream pies from a neighboring bakery, were all taken severely and suddenly ill with symptoms of gastro-intestinal irritation, those who had eaten more largely, apparently, even dangerously so, for they became so collapsed that the attending physician administered injections of brandy and ammonia, fearing that death was about to ensue.

In each of these three cases the vanilla was from a freshly-opened bottle of extract from reputable makers, and, so far as any chemical examination could show, nothing was amiss in the sample. The reason that vanilla occasionally produces such violent symptoms is at present merely a matter of conjecture, for nothing definite is known about it. Elaborate chemical investigations, however, have proven the absence of metallic poisons in most of the cases reported, and in no one case has any other known efficient cause been found to account for the symptoms presented.

The speaker had, however, some suspicion that the presence of some product of incipient decomposition in the articles which had been flavored with the vanilla, may have been the really active cause in producing the symptoms which have been presented by all the recorded cases.

DR. E. G. CUTLER read a paper on

IODOFORM POISONING.[1]

DR. JOHN HOMANS said that he had listened with much interest to Dr. Cutler's paper, and that it is one, like all his other writings, of great practical value. Having been puzzled lately to account for the appearance and persistence of nervous symptoms in a man with a compound fracture of the leg, he asked, as he had often done when in doubt in regard to diagnosis, counsel of Dr. Cutler. He described the symptoms, and the mental and physical condition of the patient, and Dr. Cutler at once asked if iodoform was used as a dressing. Being told that it was, he said that he thought it very probable that the iodoform might be the cause of the delirium, emaciation, and feebleness. He suggested that potash had better be given internally, and that if the loss of flesh and strength continued, that transfusion of a solution of potash had better be done. It should be said that iodoform has been very freely used at the hospital as a dressing during the last two years, and the box of yellow powder, with the camel's hair brush, and the hard rubber instrument for insufflation, are familiar sights in some of our wards. Indeed, dressing with iodoform has been the routine practice, and every fresh and old wound has been dusted with it.

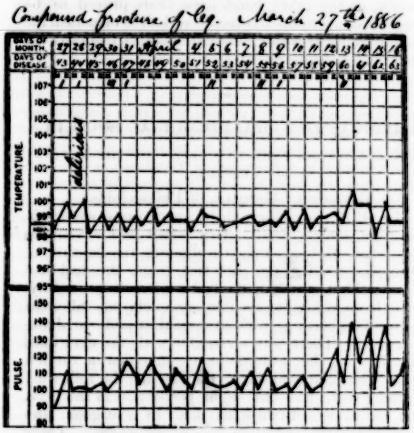
The patient is a man forty years old, brought to the hospital on February 13th, 1886, with a compound fracture of the lower third of the left leg. On entrance, the bones were wired together and iodoform was dusted over the wound. During the next twelve days the leg was dressed seven times, iodoform being dusted on each time. At each dressing, a camel's hair brush was dipped in the iodoform once or twice, and then shaken over the wound. On February 24th the leg was wired again, as the first wire had broken. On February 28th the iodoform was omitted, and a drip of carbolic acid solution was substituted (1-100). At this time the leg and foot were much swollen, and collections of pus were found and opened. On March 9th the drip was given up, and the leg, on which there was a granulating surface about the size of the palm of the hand, was enveloped in a large flaxseed poultice.

By March 17th, the swelling had greatly diminished and the sloughs had separated. A dressing of dry, carbolized gauze, charpie, and myrrh, with iodoform dusted on the granulating surface, was now employed. During the next six weeks (or about six weeks) the leg was dressed in this way seven times. Eleven days after the renewal of the iodoform, that is, on March 28th, the patient began to be delirious, and to talk at random. This state of things increased until he became insane. On April 2d he removed his splints whenever he was not watched, and was completely insane and demented, but still, when he was censured for taking off or disarranging his splints and dressings, he would weep and hope that his actions were not considered intentional.

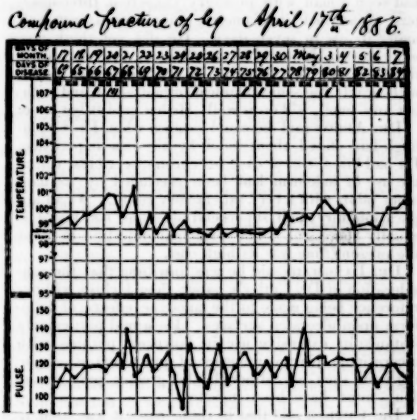
On April 3d all drugs and stimulants internally were discontinued. On April 4th he was more delirious, excited, and enraged, saw foreign bodies and animals, said his wife had been insulted, slept almost none at all, and was very restless.

April 5th. Wanted to be taken home, and would ask if the carriage was ready. He was given bromide of potash, twenty grains every two hours, and this was continued through the daytime for two weeks. During this time the patient was more quiet and slept considerably, but when awake had subsultus, and there were sordes on the tongue and teeth. He was now very weak and emaciated, and at times passed his urine involuntarily. He was given large quantities of milk, eggs, and stimulants. He spoke incoherently, had muttering delirium, and was, in short, in the condition we call "typhoid." At this time his urine was examined at the Medical College, and had a specific gravity of 1036, a slight trace of albumen, oxalate-of-lime crystals, and a few hyaline casts; no sugar.

On April 24th he seemed somewhat improved, though he still tried to get out of bed, and was very obstinate at times, and at other times frightened and timid, though quieter and more intelligent, but he still talked about going to places which his attendants had never heard of.



On April 26th Dr. Cutler saw him. When the dressings were removed from the leg, a healthy, granulating, dry surface, about two inches long, was seen, and on this rested a yellow dust of iodoform. In the urine, Dr. Cutler got a reaction of iodine with starch, but the house-surgeon did not succeed in getting this



[1] See pp. 73 and 97 of this Journal.

subsequently in later specimens. Carb. of potash in ten-grain doses was given every two hours, and later, the acetate was substituted. During all this time of debility, emaciation, and delirium, the leg has done remarkably well, in spite of the fact that he broke the wire out of the bones. He is now (May 10th) clearer and brighter, and is rapidly gaining flesh and strength. He is saner than he was, but he [2] is still crazy, and no hour goes by that he does not make an insane remark or express an insane delusion.

Here is a man with a severe injury, gradually improving locally, and gradually and slowly becoming more and more delirious; then insane, then stupid, emaciating, growing weaker, getting into a typhoid condition; and all this time his wounds are healing, and all the organs of his body, except his brain, working well. Iodoform has been used as a dressing, and its known poisonous effects resemble exactly those of my patient. The diagnosis is certain and positive, I think.

The following are the temperature charts of Dr. Homans's patient: —

DR. BRADFORD mentioned a case which occurred in a woman with cancer, who was peculiarly susceptible to drugs, her urine having been made smoky by carbolic acid applied to her cancer before operation. A large part of the breast was removed, together with glands from the axilla. There was collapse at the time of operation, but she recovered. Her temperature did not go up to 101°, but, excepting for this low temperature, she had typhoidal symptoms. The pulse was 150 and soft, respiration rapid, and there was delirium. All this time the wound was doing well. The dressing was changed to corrosive sublimate and boracic acid gauze, and in a week she was clear in mind. This is the only well-marked case seen by Dr. Bradford in his service at the City Hospital, and at the Childrens' Hospital, but he may have overlooked mild cases. Four years ago Dr. Fifield reported a severe case.

DR. GAY said that he had used iodoform very freely during the last two or three years, and had seen one case of poisoning. This was in a woman with cancer of the cervix, and whose dressing, iodoform on a cotton plug, was applied by her daughter. She had headache, loss of sleep, and nausea, but no delirium. Iodoform is a dressing that he never applies to large granulating surfaces, for which he at present prefers carbolic acid. The wound is covered with gauze, which is dusted with iodoform. Over this, if necessary, is placed oiled silk and gauze over that, the edges being dusted with iodoform. He believes that with this dressing there is no danger, and has used it, where from the debility of the patient, he would not dare to take risks. He mentioned a man who had been impaled in an accident, having a wound extending from the great trochanter to the spine of the pubes. This was packed every day or every other day with iodoform gauze. Here was a case which seemed a favorable one for poisoning, because of the extent of the surface exposed, but, in fact, no poisoning occurred. He remembered dusting iodoform on several large wounds before he knew how to use it, and he believes that, like carbolic acid, some few people are quite susceptible to it, but that in a large majority of cases it is capable of being made of great value.

DR. H. W. CUSHING, present by invitation, reported a case of necrosis of the femur for which the great trochanter was chiselled out at the Carney Hospital and the wound packed with iodoform-ribbon gauze, over which was placed a corrosive sublimate dressing. Everything went on well for three days when, although the wound continued to do extremely well, there were severe nausea, vomiting, with typhus symptoms, including delirium of a peculiar kind, the patient being coherent to the surgeon and the house-surgeon but not to others. The temperature rose to 102° to 103° on the third day, and remained there until the sixth, when it rapidly fell to 99° in the course of two days, the fall beginning at the time when carbolic acid was substituted for iodoform. Death occurred on the ninth day. On the other hand, he had

[2] Since the case was reported, the man has entirely recovered and has gone home well.

made a wound six inches long, and a third to a half inch wide in the abdomen of a dog, and packed it out of sight in iodoform for four or five days, without getting the symptoms of this paper.

DR. GREENOUGH said that he had used iodoform largely in the treatment of soft chancres during nine years, and had seen no ill results. He should be sorry to think that it was a dangerous drug, but he did not have so large surfaces to deal with as come into the care of general surgeons. It is very valuable for controlling suppuration and for promoting cicatrization. He had seen a man with an angry chancroid, three-quarters of an inch in diameter, quite recently get well under its use in seven days. He did not think any other treatment would be so efficient. A great objection to its use is its smell. It is claimed that iodol, with nearly the same chemical organization, and without any smell, will do as well. He has used it but once.

DR. ABBOT said he could confirm what Dr. Greenough had stated about iodol by his own experience. He had used it in a case of chronic cervicitis, where the use of iodoform had been precluded by its nauseous odor, with a very satisfactory result. As an application for small superficial ulcers he had found it equally successful. The principal objection to it at the present time was its high cost.

DR. LANGMAID said he was unwilling that the consideration of Dr. Cutler's paper should close without reference being made to the anodyne effects of iodoform upon ulcerated surfaces. He would particularly instance its extensive use in laryngeal phthisis with ulceration. He was unaware of any report of poisoning from such use, although the greater part of the drug must have been ingested.

DR. CUTLER said that in these cases it was used in just the proper way, a thin layer being blown upon an ulcerated surface. His table shows two cases of poisoning by the internal use of the drug, and one in laryngeal insufflation.

Dr. Cutler did not wish to be understood as deprecating the use of iodoform, he was second to no one in his high regard for the drug in its legitimate sphere, which was an application to fresh wounds or unhealthy or diphtheritic surfaces. As was remarked by Dr. Greenough, it was one of the best promoters of healing and of healthy granulation formation which we possess, but beyond a certain point its action was liable to be harmful. As soon as the surface was healthy, or granulating, the time had come for leaving off the iodoform and using some other innocuous substance, for the reason that the action of iodoform, as shown in the table of cases referred to in the paper, was not under our complete control and was liable to make itself apparent at a remote period. If the views of the observers quoted in the paper as to the absorption and ultimate fate of iodoform in the system are correct, it is evident that there is a liability to poisoning in the continued use of iodoform in all cases where a considerable hæmorrhage or other exhaustive drain on the patient has occurred. According to the theories, only that part of the iodoform proves poisonous which fails to enter into combination (as iodine) after absorption. A certain amount of iodoform is eliminated by the kidneys and other secretions as such, this presumably has no poisonous action. In the case mentioned by Dr. Gay, the conditions were the least favorable for poisoning, the gauze dressing being the one of all others from which little or no symptoms are apt to arise. The iodoform adheres to the dressing; it cannot be applied in any great quantity, and it does not come in such close connection with the tissues as in other forms, so that absorbtion is less liable to occur. The symptoms of iodoform poisoning are very like those of poisoning by iodine; one observer (Behring) has tried to divide cases according to their symptoms into true iodoform and iodine cases: this seems at present to be premature, at least. The potash compounds have been found to be non-poisonous in the blood, the soda compounds, on the other hand, have been proved to be poisonous, and in the exhibition of iodide of potash the symptoms, as we know, are quite distinct from any we have seen in iodoform.

AMERICAN OPHTHALMOLOGICAL SOCIETY.[1]

THROMBOSIS AND PERI-VASCULITIS OF THE RETINAL VESSELS,

by DR. GEORGE C. HARLAN, of Philadelphia.

Mrs. F. B., age thirty-three years, came under observation June 5, 1886. Her father and a younger sister had died of Bright's disease, the mother of paralysis. During the past two years, she had had considerable headache. She had a miscarriage in July, 1885, from which her recovery was delayed. She had a second miscarriage without special trouble in January, 1886. There was no trouble with the eyes until May 7, when she noticed dimness of vision in the left eye. This increased during the day and the following morning there was only light perception in this eye. She was examined two weeks later by a surgeon, who pronounced the condition one of embolism. There was no suspicion of specific disease. There was no uterine trouble and the heart sounds were normal. The urine had a specific gravity of 1009, contained some albumen, but no tube casts were found. Examination of the eyes showed no light perception in the left eye. The media were clear. There were hæmorrhages scattered through the retina. Some were striated, extending in long streaks along the vessels. There were three groups of white spots at the macula. With one exception all the vessels of the retina were converted into white bands. The exception was a small artery having an independent origin. The vessels were of nearly normal size. Five or six weeks later, the hæmorrhage had been absorbed, but there were no other changes. In the right eye there were several small hæmorrhages and two filmy white patches. These subsequently disappeared. In July, she had a slight attack of paralysis on the left side and examination of the urine showed some albumen and hyaline tube casts. The rapid onset and the occurrence of blindness within a few hours seemed to exclude the possibility of disease of the vessels. Embolism would not account for the condition. The speaker suggested that the partial blindness for the first few hours was due to hæmorrhage, and that the complete blindness coming on later, was due to thrombosis. Thrombosis of a whole series of vessels is however rare. Another possible explanation is that there had been for some time disease progressing in the outer walls of the vessels without giving rise to sufficient disturbance of vision to attract attention.

[1] Continued from page 90.

By way of comparison a second case was described in which the affection seemed to be a peri-vasculitis. It was that of a negro woman who had been partially blind for a long time. The right eye was the seat of a dense cataract. In the left eye V=20–100. The lens was hazy and the disk pale. Extending upward there was a large artery converted into a chalky band. Two smaller arteries exhibited the same condition in places.

A NEW TEST-TYPE,

by DR. WM. S. DENNETT, of New York.

The speaker called attention to the fact that although for twenty-five years the schools of the civilized world had been under the observation of oculists who all agree that great good would be done by periodical examinations of the eyes of scholars and although such examinations were very simple, the internal inertia of existing institutions had always prevented any continued action on the part of the schools. Among the laity there is absolutely no knowledge of what normal eyes should be expected to see. A card was presented which was designed for the use of educational institutions. It contained one set of letters and a statement underneath of the exact distance at which these letters should be seen. The desire was expressed that this or some similar card should be placed on the wall of every school-room in a conspicuous place so that it should become of necessity a familiar object and a standard of measurement that would be remembered through life.

THE POSSIBLE RETARDATION OF RETINITIS PIGMENTOSA IN THE YOUNG,

by H. DERBY, M.D., of Boston.

This affection is, as a rule, considered incurable, leading gradually to complete blindness. In America, the disease is exceedingly infrequent, the author having seen it but twenty-seven times in thirteen thousand eye cases. In 1881, a boy, three years of age, was brought to him from Western Virginia. It was observed that toward night vision diminished. There was no history of blindness in the family. Five years later he came again, accompanied by his sister, seven years of age; both children were night blind and presented the evidences of retinitis pigmentosa. Under the use of the constant current, there was improvement. A similar case of improvement under the use of the constant current, under the care of Dr. Standish, was reported.

The object of the paper was to invite discussion as to the use or non-use of such eyes for educational purposes and as to the possibility of adopting measures for delaying the progress of the organic change.

A third case, that of G. W., aged fourteen, was described. He presented the typical appearances of retinitis pigmentosa. Non-use of the eyes and the application of the constant current was recommended. He was subsequently advised by others to use the eyes freely. In five years vision diminished from three-tenths to one-tenth. This rapid progress of the disease it was thought, might have been aided by the use to which the eyes had been subjected.

DISCUSSION.

DR. WILLIAM S. LITTLE, of Philadelphia. In one case of retinitis pigmentosa occurring in a deaf mute, I have seen decided improvement in vision under the use of the faradaic current. The improvement continued for two years without change. He then went west and seven years after the applications, he was doing well, but he could not see quite as well at night as before.

In two cases coming to the Jefferson College clinic, the pigmentation had progressed so far that the vitreous also continued black. This I had never seen before.

DR. L. WEBSTER FOX, of Philadelphia. I have had the opportunity of treating a number of cases successfully. I have found that it was the negative pole that produced the good results. I also noted that if there were no enlargement of the field after three applications, improvement was not to be expected. In all the cases in which improvement took place, the bloodvessels seemed to increase in calibre and the night blindness correspondingly diminished.

DR. GEORGE C. HARLAN, of Philadelphia. I have recently seen two well-marked cases of this affection, one in a boy of seventeen years, and the other in his sister, a few years older. My faith in any form of treatment being slight, I advised that the eyes be used as long as sight remained. From the cases which I have seen, I think that there is likely to be a culmination of the disease about puberty.

DR. GEORGE STRAWBRIDGE, of Philadelphia. I should like to add a word. I tried the use of electricity in this affection thoroughly, some ten years ago. I did not obtain benefit in a single instance. I place more reliance upon the occasional use of alteratives as bichloride of mercury and iodine of potassium, looking on these cases as probably of syphilitic origin.

DR. SAMUEL THEOBALD, of Baltimore. I have had no experience with the use of electricity in retinitis pigmentosa, I have, however, seen temporary improvement from the continued use of phosphate of iron, quinia, and strychnia. One of these cases was seen when eight years of age, some ten years ago. He retains sufficient vision to enable him to perform his duties as a travelling salesman. There was no intemperance of the parents of this patient, but there was a history of a similar trouble in other members of the family.

DR. S. D. RISLEY, of Philadelphia. It has seemed to me that with the hypodermic use of strychnia, I have secured improvement in the central sharpness of vision. I have frequently seen improvement follow the use of this drug, but as far as I know, it has never been permanent. As regards the age at which the affection may develop, I have seen it in two children of the same family, occur under five years of age.

I wish to mention another fact. A young man consulted me with retinitis pigmentosa, with marked contraction of the field, and asthenopia, principally due to hypermetropic astigmatism. He was treated with alterative remedies for two years, during which time the difficulty had not materially increased. To relieve the asthenopia I ordered a weak solution of eserine, sufficiently strong to contract the pupils without causing peri-orbital pain. Under its use vision decidedly improved. He has used this solution more or less constantly for the past two years, and finds that when he is without it he is distinctly more uncomfortable.

DR. O. F. WADSWORTH, of Boston. I wish to refer to one case which in connection with those reported, shows the variable course the disease may pur-

sue, when left to itself. A young man twenty-four years of age, a divinity student, was seen in 1873, presenting typical retinitis pigmentosa, so far as the ophthalmoscopic appearances were concerned. He had well-marked night blindness. His field was only one and one-half inches in diameter at the distance of a foot. He was reading German and Hebrew without discomfort. He continued his work and I saw him eight years later. Vision was the same, but the visual field seemed to have decreased to a slight extent.

THE EQUIVALENCE OF CYLINDRICAL AND SPHERO-CYLINDRICAL LENSES,

by Dr. Edward Jackson, of Philadelphia.

The paper was intended to demonstrate the laws of such equivalence, showing that equal crossed cylindrical lenses are optically equivalent to a spherical lens of the same refractive power. Crossed cylinders of unequal refractive power may be regarded as crossed cylinders of equal refractive power combined with a third cylindrical lens, or as their equivalent, a spherical combined with a cylindrical lens. It was proven that any two cylindrical lenses with their axes placed obliquely, the one to the other, might be represented by crossed cylinders, that is, cylinders with their axes perpendicular to one another, or by their equivalent in the shape of a sphero-cylindrical lens. Hence that any number of cylindrical lenses with their axes placed in different directions are optically equivalent to a single sphero-cylindrical lens. To determine the sphero-cylindrical equivalent to any two cylindrical lenses, construct a parallelogram, two sides of which are proportional to the refractive power of the given lenses, the angle included by these sides being double the angle made by their axes. Then the diagonal which cuts this included angle, will be proportional to the cylindrical portion of the desired equivalent and to get the spherical portion it is only necessary to subtract one-half of this cylindrical equivalent from half the sum of the cylinders given.

DISCUSSION.

Dr. William S. Little, of Philadelphia. With reference to the practical side of this question I may say that in about one-half of my cases of mixed astigmatism, the patients have preferred crossed cylinders to their equivalent sphero-cylinder. In using a sphero-cylinder it is essential that it be accurately centred.

Dr. G. Hay, of Boston, read by title a paper on

THE COMBINATION OF CYLINDER LENSES.

The committee to whom was referred the consideration of the proposition with reference to the organization of a Congress of American Physicians and Surgeons, reported the following resolutions and recommended their adoption:

Resolved, that a committee of five be appointed by this Society and be authorized to confer with committees from other medical societies with regards to the organization of a convention or congress of such societies and report at the next meeting of this Society.

Resolved, that it is the sense of this Society that its welfare would be put in peril by any alliance or co-operation which would interfere with its autonomy or independent meeting.

These resolutions were adopted and the following committee subsequently appointed:

O. F. Wadsworth, Boston; C. S. Bull, New York; George C. Harlan, Philadelphia; Samuel Theobald, Baltimore, and B. E. Fryer, Kansas City.

Adjourned until three o'clock.

AFTERNOON SESSION.

The first paper of the afternoon session was a report of

TWO HUNDRED AND SIXTY-THREE CASES OF CATARACT EXTRACTION WITH PARTICULAR REFERENCE TO THE AFTERTREATMENT,

by George Strawbridge, M.D., of Philadelphia.

Two hundred and twenty-three of the above cases had never been reported. The operation was performed by the modified flap extraction in which the incision lies mid-way between the old Græfe incision and the corneal flap incision. It avoids the risks of both of these methods and gives a sufficiently large opening. An iridectomy in an upward direction was always performed. Formerly the lens was removed by pressure with the spoon directly on the cornea, but fearing injury to that tissue, during the past year, pressure with the finger on the closed eye-lid had been substituted. The results had been as follows: successful cases, 85.2 per cent., partial successes, 8.1 per cent., and failures, 6.7 per cent. Those cases were classed as failures in which fingers could not be counted at a distance of one or two feet. In twelve cases absolute loss of the eye occurred. These were lost by choroiditis with one exception, which was due to choroidal hæmorrhage.

After the operation the eye was thoroughly cleansed and for the past two years a solution of boracic acid (two per cent.) had been employed. The speaker's former plan had been after applying a bandage to put the patient to bed in a darkened room, keeping them in bed for four to six days. Two-thirds of the cases had been treated in this way. He had found this plan exceedingly debilitating in elderly individuals, and during the past eighteen months he had gradually given up this plan so that during the past six months, the patients were, practically speaking, kept in bed only twenty-four hours. The room is as light as any ordinary room, the first element in the treatment of old people is to make them comfortable. If at the end of twenty-four hours, everything is doing well the patient is allowed to move about the room. No unsatisfactory result had followed this plan.

The speaker had employed in some cases cocaine. In one case in which a four per cent. solution was used a violent purulent inflammation began within twenty-four hours and resulted in total loss of the eye. Subsequently he had employed it without unpleasant results. His plan is to use a two per cent. solution, drop in one drop, wait a minute and drop in a second drop and use only two drops. As much anæsthesia as is desirable is thus obtained. He had never employed any antiseptic except the two per cent. solution of boracic acid, and while this does no harm he thought that it did little good.

He attaches much importance to stimulation after the operation in elderly people, the use of whiskey is begun a few hours after the operation.

(To be continued.)

Medical and Surgical Journal.

THURSDAY, AUGUST 5, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $6.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

283 WASHINGTON STREET, BOSTON, MASS.

SCARLATINA AND MILK.

THE English Local Government Board has issued an important pamphlet, now before us, containing papers, on certain observed relations between scarlatina in London and milk from a dairy farm at Hendon; on the anatomy and pathology of the disease observed among the cows of the Hendon Farm; on the signs and symptoms of a disease observed among the cows of the Hendon Farm. Of these papers the first two are reports made to the Board, at its request, respectively by Mr. W. H. Power, one of its most competent inspectors, and by Dr. E. Klein, of the Brower Institution, London; the third paper is a portion of a communication read at one of the meetings of the British Epidemiological Society by Dr. James Cameron, local medical officer of health at the town of Hendon. These papers are preceded by an introductory report by the medical officer of the Local Government Board, Dr. George Buchanan; and taken together they constitute one of the most valuable contributions made for some time to our knowledge of the relations between infectious diseases in man and in animals. It is not too much to expect that as a result of these investigations additional checks may be applied to the increase and distribution of so common and dangerous an epidemic disease as scarlet fever, or that possibly a method of inoculation against scarlet fever as effective as vaccination against small-pox is about to be placed in our hands.

In the development of modern sanitary science and preventive medicine, each year shows more clearly the intimate hygienic dependence of man upon his animate and inanimate surroundings. Methods, previously unsuspected though in frequent operation, for the distribution of the poisons of infective diseases are being demonstrated. Among such none have been more frequently or clearly incriminated than milk-supplies, and milk has been proved a most effective medium for the cultivation of these disease germs.

The English Local Government Board, through its accomplished health officers and inspectors, has been a pioneer in these investigations of the relation between local milk-supplies and epidemic outbreaks of typhoid fever, diphtheria and scarlet fever. In no less than fifteen instances one or other of these diseases has been shown upon sufficient evidence to have been distributed with the milk service of the families invaded. In the scarlatina outbreaks it was at first supposed that the milk had been infected by human agency, but a more exact study of successive epidemics caused a distrust of this explanation, and a suspicion that the milk was in some way infected by the cow.

In 1882, Mr. Power investigated and reported on a scarlet-fever epidemic distributed with a certain milk-service. In this instance two facts were established: "the one, that a cow, recently come into milk had been suffering from some ailment, seemingly from the time of her parturition, of which loss of hair in patches was the most conspicuous manifestation; the other, that there existed no discoverable means by which the milk, which had coincided with scarlatina in its distribution, could have received infective quality from the human subject." It was not possible, however, to establish a relation between ailment of any particular cow and the disease spread from the farm furnishing the milk. At this time Dr. Klein — at the instance of the Board — made some experimental observations as to the susceptibility of animals to human scarlatina which convinced him that a definite disease was producible in the cow by means of scarlatina-infection, producible most readily when the cow was in milk — and that this disease was communicable from one animal to another by inoculation.

As a result of these investigations in 1882 a presumption merely was established that the epidemic of scarlet fever established by a certain milk-supply was the consequence of a malady in certain cows, and here the matter rested.

In December, 1885, the medical officer of health of Marylebone, London, reported a sudden and extensive outbreak of scarlatina that appeared to be associated with the distribution of milk from a particular retailer who derived this supply from a dairy farm at Hendon, though the sanitary circumstances of the farm itself, and the health of the employés, proved upon inspection remarkably good. Mr. Power was detailed to make inquiry into the whole case, both in London and at Hendon. In due course the point was reached of excluding external scarlatina, of associating the importation of particular cows into the Hendon farm with presence of scarlatina in London districts, and of connecting by a series of parallel events, the milk furnished by those cows, and related cows, with the peculiarities of scarlatina prevalent among consumers of the Hendon farmers' milk. Subsequently it was learned that the suspected milk, which was ordered by the inspectors and the farmer to be thrown away, had been actually consumed by some poor families who begged it from the farm laborers; its consumption being followed after the usual interval by an outbreak of scarlatina. Still later it was proved that the infectiveness of the milk from a certain shed in the dairy farm coincided with the introduction of cows having

diseased appearances — vesicles and ulcers — about the udders and teats, with a loss of hair from the tail and back particularly, in some instances, and that the infectiveness of the milk of cows in other sheds corresponded with the transfer of the diseased cows to the other sheds or the development of the same conditions by other cows.

The inquiry of Mr. Power rested at this stage, and afforded strong circumstantial evidence that a constitutional disease existed among the cows of the Hendon farm competent to produce scarlatina among human consumers of the cows' milk.

The special features and pathology of the disease were described and studied by Drs. Cameron and Klein. Dr. Klein's study of its pathology was made at the request of the Board, and he states the outcome of his investigations as follows: By inoculating the virus directly taken from the local disease (the ulcer on the teats) of the cow into the corium of the calf, the same local disease is produced, namely, a change in the skin, which commences as a congestion of the papillæ and corium, and with exudation of fluid and leucocytes. This leads, in the superficial parts of the epidermis, to the formation of cavities, which ultimately lead to the formation of an ulcer. But the virus, in the form of an artificial cultivation of the streptococcus derived from the above ulcer of the cow, when inoculated into the subcutaneous tissue, that is, when introduced almost directly into the vascular system, sets up a general disease, resembling, to a considerable degree, in its anatomical features, human scarlatina. The changes in the kidney completely coincide with those in acute scarlatinal nephritis in man.

As respects the part that cows' milk may play in the communication of the disease, it appears that the milk, when pure, does not contain the organism, but the milk, during the act of milking, is liable to become contaminated by the fingers of the milker bringing down into the milk particles from the ulceration on the teat, and for such an organism, the milk affords a peculiarly good medium in which to multiply.

The results of the *inoculation* into the human subject of a milk sub-culture, or of the *feeding* of calves with such milk-cultures as appear to have been fed to children, are links still wanting to complete the chain of evidence offered by Dr. Klein; but, as we indicated at the beginning of this brief summary of these interesting inquiries, a point seems to have been reached from which the attainment of practical advantages to humanity may reasonably be anticipated.

BILIOUSNESS.

IT is a pathological law that all organs are liable to excess, diminution, and perversion in their functions. The bile-producing function of the liver is especially prone to undergo augmentation, and the causes which give rise to such excess are frequently operative with some persons, and almost constantly with others. Such causes are generally alimentary, although other influences, such as excessive heat, malaria, and certain animal, vegetable, and mineral poisons may be promotive of inordinate biliary secretion; hereditary predisposition is a powerful determining factor, and there is a certain temperament associated with dark eyes, dark hair and skin, which probably, with no very good foundation, is supposed to belong especially to the "bilious" constitution.

Placed at the very gateway of life, with the special office of elaborating albuminoids and carbo-hydrates before they are fit to enter the circulation and subserve the wants of the economy, the liver has, so to speak, to "work over" all the products of digestion absorbed by the portal vein, and is physiologically influenced both by the quantity and the quality of these aliments. While the ingestion of vegetable matters and cereals caused diminution in the biliary secretion in animals, the subjects of experimentation (experiments of C. S. Schultz), the secretion was increased by albuminoids, and if fat in excess was added to the daily rations, not only was the biliary flow augmented, but coincidently, the cholesterine and other fatty matters of the bile were increased, and the bile had a greenish appearance.[1] Over-feeding, moreover, augmented the flow of bile from the fistula. But this is not all; excess in food or drink in animals under experimentation, as also in Alexis St. Martin, and in Richet's patient with gastric fistula, caused gastro-duodenal catarrh with reflex irritation of the liver, an increased bile production being the result. Here the blood became contaminated with both bile and the crude products of digestion. Clinical experience has abundantly confirmed these experimental observations, and almost everybody has at some time personally suffered from the symptoms due to biliousness from excess of bile production.

If men are prone at all times to errors in diet, such errors are more likely to be committed at the present season, when, according to a popular impression, the dog star exerts its pernicious, depressing influence; when, too, a dietary which might be normal in cold weather would be unnecessary and harmful. Although the activity of all the chemico-vital phenomena is lessened, and the nutritive metamorphoses are slowed, while the diminished craving for food warns against full indulgence, it is, nevertheless, true that the warning is too seldom heeded, appetizers are sought for, albuminoids and carbo-hydrates in abundance are devoured, and the jaded digestive organs are teased to do work for which they have become unfitted.

It must be acknowledged, in this connection, that there has been much confusion as to what is denoted by this word *biliousness*, a word for which our Continental friends have hardly any good equivalent. A person is *bilious* when he is suffering either from excess or diminution of bile production, and the pathology and symptoms of both conditions are not so wide apart as one might at first suppose, for an over-

[1] Bouchardat and Sandras.

stimulated liver eventually becomes exhausted and unable to form bile. This is the way in which Harley explains the connection between over-stimulation of the liver and suspended biliary secretion.

"The first stage of hepatic capillary congestion leading to hyper-secretion of bile leads to a second stage of diminished biliary secretion by pressure of the engorged capillary vessels and bile ducts on the secreting hepatic cells. Hence the bile ceases to be secreted in its usual quantity, the biliary coloring matter and other bile elements remain behind in the circulation, and accumulating there, give rise to the chain of symptoms usually included in the generic name of a bilious attack; sallow complexion, headache, giddiness, disordered vision, sickness, and prostration, these, again, are the results of the toxic effects of the biliary substances on the nervous system. This form of biliousness may be looked upon as a slight or incipient stage of jaundice." [2]

What is commonly known as an acute bilious attack is more properly an acute indigestion, the *embarras gastrique* of the French. A person, we will suppose, has indulged in a surfeit; he has giddiness, frontal headache, and general prostration; there is a furred tongue and a bad taste in the mouth; there is nausea and vomiting, and perhaps diarrhœa. If there be bile in the vomitus and dejecta, it is because the liver has been secondarily disturbed in its functions. In fact, the excessive biliary secretion has been looked upon as salutary, as in fact, an effort to clear the clogged and embarrassed *primæ viæ*. The derangement is gastro-intestinal, rather than bilious. If the liver is involved in every severe irritation of the digestive tube, this is owing to the solidarity which characterizes the functions of all the chylopoietic organs.

If there be headache accompanying these attacks, owing probably to reflex excitation of certain sensory branches of the fifth nerve, it is also true that neurosis of the fifth (migraine) may reflexly excite bilious vomiting, and this accounts for the fact that migraine is often confounded with "biliousness."

The observations made by Dr. Beaumont more than fifty years ago on Alexis St. Martin, must still be cited (as they have recently been by Dr. Lauder Brunton)[3] in explanation of the phenomena of acute biliousness. After excesses in eating and drinking, Beaumont found St. Martin's stomach covered with livid spots and apthous patches; the gastric secretions were mixed with ropy mucus; the digestion was slower than usual, or suspended altogether. A little later the symptoms of biliousness were superadded. The usual appetite was gone, the tongue was covered with a thin yellowish coat. The countenance was sallow and on the interior of the stomach there were several deep-red patches. A muslin bag which had been introduced with some food in order to test the rapidity of digestion, when drawn out was covered with a coat of mucus and yellow bile. On the succeeding day the coats of the stomach were still unhealthy and of a deeper red than naturally, with patches of a still deeper color and the mucous covering abraded in places." This venous congestion indicated stasis in the radicals of the portal vein, and hepatic engorgement. Beaumont, who records several such instances in his book (pages 100, 118, 251–4, 270,) states the benefit which in one instance was derived from a purgative dose of calomel, "which removed all the foregoing symptoms and the diseased appearance of the inner coat of the stomach." On another occasion his patient was restricted from a full and confined to a low diet, and simple diluent drinks, with restoration *ad integrum* of the disordered viscera, and return of health and appetite.[4]

Although the bile acids themselves are sufficient toxic when in excess in the circulation (see experiments of Harley, Feltz and Ritter, Graham, Brown and others), and although it has been proved that these acids in jaundice have a specially depressant effect on the nervous centres, being indeed violent cerebral poisons — whence *melancholy* was anciently attributed, and not without some reason to *black bile*, as the derivation of the word shows — yet *biliousness*, in its common acceptation, is vague and indefinite compound of cholæmia lithæmia and stercoræmia; and as factors in the causation of the morbid syndrome we have mal-elaborated peptones and poisonous ptomaines.

The treatment of biliousness is prophylactic, alimentary and medicinal. Prophylaxis is concerned with avoidance of all the known causes, whether of a toxic, malarial or alimentary character. A plain diet, of bread, milk, oatmeal, vegetables and fruits with lean meat or fresh fish in moderation, and abstinence from alcoholic stimulants seems to be the ideal fare for the biliously predisposed. This kind of diet is especially applicable for hot weather when albuminoids are apt to clog the portal system, and pastries are an abomination, and when a broiled schrode, a little chicken or mutton broth with bread and stewed fruit will make a more healthful meal than the more sumptuous fare of a modern fashionable dining-saloon.

Exercise in the open air is of recognized utility in promoting oxidation and elimination, enhancing the digestive and assimilative processes, and lightening the burdens of the liver. Moreover, exercise (whether by rowing, horseback-riding, gardening, walking) hinders absorption of bile by the hepatic venous radicals, and promotes the passage of that fluid into the duodenum, through the increased compression exerted on the liver by the diaphragm and abdominal muscles; this is in accordance with a recognized physiological law.

The victim of an acute bilious attack will generally get righted in a few days by, first, abstinence from all food, then a diet of porridge and milk, or skimmed milk alone, and a very gradual return to solid food, which for several days should be restricted to toast, a little lean meat, or broiled fish, with some succulent

vegetables or ripe fruit. As for medicines, saline aperients, such as sulphate of soda, Epsom or Rochelle salts in full doses in the morning, or the now fashionable tumblerful of Hunyadi Janos will generally suffice to clear the *primæ viæ;* the latter has especially a reputation for evacuating bile. The striking relief obtained by free bilious evacuations has often been remarked, and the veteran transgressor resorts to his blue pill or podophyllin with every recurrence of his malady. Of late enonymin has come much into use as a cholagogue.

Harley recommends to persons who seem to have a more than usual tendency to biliousness traceable to sluggish biliary secretion, and where there seems also to be defective nerve action, small doses of nux vomica or strychnia after their meals. This may be combined with belladonna and aloes as in the aloin, strychnia and belladonna pill. The bilious person is generally constipated, hence such a pill has a special utility. Fothergill's pill of ipecac, capsicum, and pil. aloes et myrrh. has done good service in such cases. Nitro-muriatic acid and taraxacum have a reputation which is probably not altogether built on imaginary results. But bilious dyspeptics, while they should be attentive to the functions of eliminations (and doubtless the ancient predilection for purgatives has been justified by modern scientific research which finds in intestinal septicæmias and alkaloids of putrefaction, many of the evils formerly attributed to peccant humors and atro-biliary disorders), should aim especially to be good hygienists and learn to live right, but this is counsel which everybody gives and nobody takes.

POISONING BY IODOFORM.

Consequent upon the rapid and wide-spread adoption of iodoform during the last few years in general surgical and gynæcological practice, a number of cases of serious and even fatal results have been reported. And it is altogether probable that the actual number and instances of poisonous action is much greater than statistics show, from failure of the attendants to ascribe to the true cause some of the outward symptoms of the post-operative condition.

The admirable paper on the subject which we have had the pleasure to lay before our readers in the last and the current numbers of the Journal, gives the particulars of some seventy-seven cases of iodoform poisoning and represents a pretty thorough canvass of the medical literature bearing on the subject.

The symptoms observed in persons engaged in manufacturing processes which involve contact with iodine compounds are not unlike those following the use of iodoform in susceptible subjects. Among them are the persistent taste and smell of the drug, impairing appetite and digestion, headache, sleeplessness and delirium, the latter being usually of a melancholy character, and in extreme cases passing into absolute apathy, with involuntary dejections, rapid feeble pulse and progressive marasmus. The pulse has often a rapidity out of proportion to the degree of elevation of its temperature, but a moderate febrile movement is not uncommon and after operative cases offers an apparent discrepancy to the aseptic condition of the wound.

The inappetence and the mental depression are among the first symptoms to strike the attention. The danger of these untoward effects seems to depend, apart from idiosyncrasy, on circumstances which hinder the perfect combination of such iodine as is set free in the organism, among those circumstances being blood changes, quantitative and qualitative, and an excessive amount of the drug used. A frequent renewal of the dressing and the maintenance of pressure are factors increasing the chances of iodoform absorption.

The detection of iodine in the urine of the patients suffering with these symptoms and having been exposed to the action of the drug, is absolute confirmatory evidence of the nature of the difficulty.

Fortunately the chemical test for iodine is characteristic and is readily applied. It is a significant fact that some of those operators who use iodoform solely as a disinfectant, although employing it very largely, have had less unfavorable effects following it than those who have combined its use with that of other antiseptics, carbolic acid, for instance. Hence Mosetig-Moorhof offers the plausible theory that the carbolic acid sets up renal irritation, from which the iodoform fails of being properly eliminated and therefore causes toxic symptoms.

MEDICAL NOTES.

— On July 3d, the English Local Government Board issued an order providing that, between that date and November 1st next, "no rags from Italy shall be delivered overside, except for the purpose of export, nor landed in any port or place in England or Wales." This step has been taken in view of the existence of cholera in Italy.

— A gunshot wound of the heart is reported in the *Indian Medical Gazette*, where the patient lived forty-two hours after a bullet had pierced the seventh rib, left lung, left and right auricles, and right lung. Bryant (Circular No. 3, War Dep. Washington) cites a case in which the patient survived a wound of the right auricle for fifty hours.

NEW YORK.

— Sanitary Inspector Goldschmiedt has made a report to the Board of Health on the condition of the old Deborah (Jewish) Nursery, on East Broadway, where there are, at present, sixty children of a more advanced age than those belonging to the new Nursery, situated a few doors away. It will be remembered that some time since, an epidemic of typhus fever broke out in the latter institution, and that, in consequence, all the inmates were transferred for a time to North Brother Island, in the East River, in order that the buildings might be thoroughly cleansed and disinfected. Dr. Goldschmiedt reports that, in making an

inspection of the old Nursery, he found the cellar foul, the plumbing and ventilation defective, and the garret stored with rags and filthy clothes; and he recommends that action be taken to compel the managers to put the premises in a satisfactory sanitary condition, especially as it has been ascertained that the outbreak of typhus in the new Nursery started from a case in this one.

— In consequence of the neglect of the authorities to provide the means for the maintenance of the usual summer corps of physicians for visiting the tenement-house population in their homes, the St. John's Guild has now organized a medical corps for this purpose, who, in addition to prescribing for the sick children met with which are unprovided with attendance, distribute tickets for the Guild's Floating Hospital excursions and the Seaside Nursery. The Sick Children's Mission of the Children's Aid Society also still maintains its tenement-house service, and now has a corps of fourteen visiting physicians. The Mission has had distributed among the poor throughout the city large numbers of printed cards, conveying the information that any family whose means will not admit the employment of a private physician, can obtain one free of charge, by applying at the office of the Superintendent, in East Broadway.

Miscellany.

ORDER TO CUSTOMS OFFICERS IN REGARD TO IMPORTATION OF OLD RAGS.

Acting-Secretary of the Treasury, Fairchild, issued July 27th, the following instruction to Customs Officers in regard to importation of old rags: "All old rags imported into the United States in vessels which have passed local quarantine at the port of importation will be admitted to entry in the same manner as other imported commodities, that is to say, without requiring special permits from health officers as to their landing. The fact that the vessel has passed quarantine will be considered as sufficient evidence that her entire cargo is free from infection." This will put the responsibility for the detention of imported rags upon the local Boards of Health, where it belongs.

NINTH INTERNATIONAL MEDICAL CONGRESS.

Circular No. 2, concerning the Ninth International Medical Congress, to be held at Washington, has been recently received. The Congress, it is proposed, will assemble at Washington, Monday, September 5, 1887, at 12 o'clock, noon, and will consist of such members of the "Regular Medical Profession" as shall have registered and taken out their ticket of admission, and of such other scientific men as the Executive Committee of the Congress shall deem it desirable to admit. A list of the officers of the Congress is given.

REPORTED MORTALITY FOR THE WEEK ENDING JULY 24, 1886.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 2,626: under five years of age 1,449: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 933, consumption 281, lung diseases 111, diarrhœal diseases 690, diphtheria and croup 86, whooping-cough 39, typhoid fever 38, measles 27, scarlet fever 24, malarial fever 15, cerebro-spinal meningitis five, puerperal fever four, typhus fever two. From typhoid fever, Philadelphia 14, New York six, Boston, St. Louis, District of Columbia, Pittsburgh, and New Bedford, two each, Baltimore, Cincinnati, Providence, Charleston, Salem, Chelsea and Northampton one each. From measles, New York 14, Pittsburgh six, Baltimore five, Cincinnati and Nashville one each. From scarlet fever, Philadelphia and Pittsburgh six each, New York four, St. Louis three, Providence two, Boston, Cincinnati and Springfield one each. From malarial fever, St. Louis six, Charleston three, New York four, Baltimore two. From cerebro-spinal meningitis, New York two, Worcester, Fall River and Chelsea one each. From puerperal fever, St. Louis two, Boston and Worcester, one each. From erysipelas, St. Louis, Pittsburgh and Providence one each. From typhus fever, Philadelphia and Springfield one each.

In the 19 cities and greater towns of Massachusetts, with a population of 930,061 (population of the State 1,941,465), the total death-rate for the week was 24.27 against 21.27 and 18.76 for the two preceding weeks.

The meteorological record for week ending July 24, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 24, 1886, TO JULY 30, 1886.

BROWN, JOSEPH B., colonel and surgeon. Retired from active service, July 26, 1886. S. O. 171, A. G. O., July 26, 1886.

GIBSON, J. R., major and surgeon. Ordered from Department East to Department Missouri, on expiration of leave of absence granted in S. O. 158, c. s., A. G. O.; S. O. 168, A. G. O., July 22, 1886.

BENTLEY, EDWIN, major and surgeon. Ordered for duty as post-surgeon, Fort Davis, Texas. S. O. 92, Department of Texas, July 22, 1886.

TAYLOR, M. K., major and surgeon. Granted leave of absence for one month with permission to apply for one month's extension. S. O. 77, Department of Missouri, July 24, 1886.

MIDDLETON, PASSMORE, major and surgeon. Ordered to Department East from Department Missouri. S. O. 168, A. G. O. July 22, 1886.

GIRARD, JOSEPH B., captain and assistant surgeon. Granted leave of absence for three months with permission to go beyond sea. S. O. 170, A. G. O., July 22, 1886.

ROBINSON, SAMUEL Q., captain and assistant surgeon. Ordered for duty as post-surgeon, Fort Brown, Texas. S. O. 92, Department of Texas, July 24, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING JULY 31, 1886.

LUNSDEN, G. P., passed assistant surgeon. To duty, Marine Barracks, Washington, for month of August.

CORDEIRO, F. J. B., assistant surgeon. Ordered to Receiving Ship, "Minnesota."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE HOSPITAL SERVICE FOR THE WEEK ENDING JULY 24, 1886.

CARMICHAEL, D. A., passed assistant surgeon. Granted leave of absence for thirty days, July 24, 1886.

MAGRUDER, G. M., assistant surgeon. To proceed to Cairo, Ill., for temporary duty, July 22, 1886.

DEATH.

Died in Lawrence, Mass., July 28, 1886, Eugene Stephen Yates, D.D., M.M.S.S.

Address.

MEDICINE IN THE UNITED STATES AND ITS RELATIONS TO CO-OPERATIVE INVESTIGATION.

THE ANNUAL ADDRESS IN MEDICINE DELIVERED BEFORE THE BRITISH MEDICAL ASSOCIATION, WEDNESDAY, AUGUST 11, 1886.

BY JOHN S. BILLINGS, M.D., LL.D., EDIN., SURGEON, U. S. A.

Mr. President, and Gentlemen of the British Medical Association: You all know that the representative of the American medical profession first selected by your executive committee to deliver the address in medicine to-day, was the late Dr. Austin Flint, Sr., of New York, whose death last March is, therefore, a great and direct loss to you as well as to America. Every English physician knows Dr. Flint by reputation and through his writings; but only those few of you who were so fortunate as to know him personally, can fully appreciate the magnitude of the loss which the medical profession has sustained in his death.

This is not the time and place to attempt to pronounce a fitting eulogium upon him and his work, and I shall, therefore, only say that my deep personal sorrow for his removal is mingled with sympathy for the members of this Association, who have been thus deprived of the pleasure of hearing him state in person some of the results of his long and wide experience. The loss is not a total one, it is true, since he had, fortunately, completed his address on "The Medicine of the Future," which has been published, and has, no doubt, been read by all of you; but in this case the printed page is by no means a satisfactory substitute for the spoken word.

In accepting the request, with which I have been honored by your council, that I should attempt to take his vacant place on this occasion, it is with a full understanding of my inability to fill it that I stand before you.

The request came at a time when I was hard pressed by official duties, and had neither leisure nor opportunity to undertake any special research; hence, to avoid violating one of my favorite Scotch maxims, namely, "That which you do not know, tell that not to any one," it was necessary to select some subject to which I had already given consideration, and which at the same time would probably be of interest to English physicians.

Reflection on these restrictions soon brought the field of selection into narrow limits, almost into "a small intercept of space of one dimension," as a mathematician would say.

What is the significance of this invitation extended for the first time to a physician of another country, and that country the United States, to come to this annual gathering of the medical men of Great Britain and give the address in medicine?

Does it not mean recognition of the unity of medicine, of the utility of coöperation, of the fact that we have common interests, and that the time has come when it is desirable to hear from the outlying younger branch of the family with a view to mutual pleasure and profit in the future? So it seems to me; and I propose, therefore, to call your attention briefly to some points relating to the present condition and future prospects of medicine in the United States, and to the direction in which you may reasonably hope and expect from that country in the future the most useful coöperation in the improvement of medical science and art. I believe that these must be matters of interest to you, and that I can perhaps make clear certain peculiarities which do not seem to be as generally understood on this side of the Atlantic, as it is desirable that they should be, to insure sound judgment upon some of the results observed.

In the first place, permit me to call your attention to the fact that it is hardly possible to make any statements with regard to medicine in, or the medical profession of, the United States as a whole, which shall be definite and at the same time distinctive; that is, which will not apply almost equally well to medicine and the medical profession in other countries. This is due to the fact that there are great differences in the organization of the profession in different parts of America, so that what is true of one State would not be true of another; what is required as to fitness or qualification to practice in one place is not required in another; and the country covers so many parallels of latitude and meridians of longitude, making the conditions of life so diverse, and producing such differences in the prevailing diseases, that a man who is fairly qualified to practice in one section may be poorly fitted to treat the endemic diseases of another.

As in painting a picture, it is best to locate and define the shadows first, and deal with the lights afterward, let us begin by considering some of the things that American physicians complain about; in other words, some of their supposed grievances. One of these is that the profession is overcrowded; that there are too many doctors, both *in esse* and *in posse*, and that this is due to too low a standard of education, and to the want of legal restrictions as to the qualifications which shall give a man the right to practice. The feelings of some of our physicians on this subject are in full accord with those of the good old New England deacon who told the village scapegrace seeking admission, that "he thought the church was about full."

Now what is the number and distribution of medical men in America? Statistics gathered in 1883,[1] showed that in the United States and Canada there were 90,410 persons calling themselves physicians, being in the proportion of 1 to every 600 of population. In Canada alone, there were 3,487 physicians or 1 to 1,112 of population. If we take the figures of our last census, of 1880, the proportion of physicians reported, is 1 to 589 of population, or 17 per 10,000. In England and Wales, by the census of 1881, the proportion of physicians is only 5.8 per 10,000, but these figures are not properly comparable with those of the United States, because they do not include unregistered persons. If the same classes were included that are counted in the United States report, I presume that the proportion would be about 9 per 10,000, or a little more than half that in the United States.

In the United States the proportion to the population of those who call themselves physicians varies greatly in different localities; thus, in Colorado there are 29.3, in Indiana 25.2, in Oregon 24.3, and in Arkansas 23.5 per 10,000; while in New Mexico there were only 6.6, in South Carolina 9.2, and in North Carolina 9.7 per 10,000.[2]

[1] Illinois State Board of Health Report, 1884.

[2] A map of the United States was here shown, on which the proportion of persons calling themselves physicians to the population in the several States was indicated by different shades of color.

It is not easy to give satisfactory reasons for these differences; we can only say that they do not depend to any great extent upon local legislation. The proportion of physicians is generally lowest in the Southern States lying east of the Mississippi, and highest in those regions where immigration has recently been active. If we compare, by localities, the proportion of physicians to the population with that of clergymen and lawyers, we find some curious differences. It seems that the lawyers in the United States number 12.7, while in England and Wales they are 6.6 per 10,000, but that on the other hand the clergymen are 14.6 in England and 12.8 in the United States per 10,000 of population. In many instances it seems that where the lawyers are most numerous the supply of clergymen is smallest. I believe that a fair proportion of physicians to population is about 1 per 1,000, which is not far from the actual proportion in England, while the true proportion of practicing physicians in the United States is about 1 in 750. We must admit, then, that there is at all events no scarcity of physicians in the United States, and, as we have over 80 medical schools at work, besides a fair proportion of medical immigrants, there is no immediate danger of any interruption to the supply.

Let us now consider the second head of the complaint, namely, that the standard of education is too low. There is ground for this, considered with reference to some localities, but not for others. I said a moment ago that a man might be fairly qualified for practice in one part of the country, and yet find himself at a loss in another. This needs a little explanation, which I can, perhaps, give most easily in connection with a map of the United States, which I here show you. This map, which was prepared for a very different purpose, indicates, by different shades of color, the relative proportion of deaths reported as due to malarial disease to the total number of deaths in different parts of the country, for the census year 1879–80. You will note how comparatively light the tint is in the north and north-east, and how dark the shades become in the south and in the valley of the Mississippi, thus indicating the great differences which exist as to the prevalence and deadly effects of the malarial poison in different sections of the country. It is in some of these low-bottom lands and swampy districts that we meet with cases of congestive chills and of malarial hæmaturia, cases in which the patient has been described as being "a mere appendage to a huge malarial entity, an incident of a miasmatic cataclysm." Furthermore, this strip of land bordering on the Gulf Coast is in the yellow-fever zone, and has, heretofore, been repeatedly desolated by this pestilence.

As compared with the North and East, much of this malarious region is a thinly-settled country, an almost purely agricultural country, and not a rich country. I need hardly tell you that the physician who has received his chief clinical instruction in the office of his preceptor in Vermont or New Hampshire, supplemented by distant glimpses of a few cases in hospital in Boston or New York, will find himself at a loss, at first, in dealing with the emergencies of daily practice in Arkansas and Mississippi. He will be subjected to influences which, at times, are dangerous to one who is not acclimated, and which tend to produce depression of spirits, want of energy, and bad health. He will not have free and constant access to scientific companionship, nor be stimulated by the influence of learned societies, and he cannot avail himself of the ordinary sources of amusement, education, and rest, such as art galleries, the drama, libraries, and museums, etc., which are found in the large cities. Moreover, the pecuniary reward which the practitioner, in many of these places, can reasonably hope for, is comparatively small.

Taking all these things into consideration, it is clear that if a man, after spending from six to eight years, and from one to two thousand pounds in acquiring such a general and professional education as it is now considered that a skilled physician should possess, then settles in such a region, with the prospect of an average income of from £150 to £200 per year, it is not from pecuniary motives alone. There are such men in such places — men who are not only highly educated and skilled practitioners, but who are also original investigators and thinkers. It was within the limits of this malarial shadow that the foundation of modern gynæcology was laid by Marion Sims, of abdominal surgery by McDowell, Battey, and Gross, of an important part of the physiology of the nervous system by Campbell. Nevertheless, the rule holds good that malaria and science are antagonistic; the exceptions prove the rule.

Nor can the inducements for highly-educated physicians to settle in thinly-settled localities be made stronger by any form of penal or restrictive legislation. Any attempt to fix a standard of requirements or qualifications for practice which shall be the same for such rural districts and for the large cities and manufacturing towns, must result in the adoption of what competent judges would consider so low a standard as to be ridiculous and useless. The demands are widely different, and corresponding differences exist in the sources of supply, that is, in the medical schools.

There is a class of medical schools in the United States whose object is to give the minimum amount of instruction which will enable a man to commence the practice of medicine without much danger of making such serious and glaring blunders as will be readily detected by the public. There are other schools whose aim and object is to make fairly well-trained practitioners, the general character of the instruction given in these being substantially the same as that given in your English hospital medical schools. The results of such a three years' graded course of instruction in medicine as these schools furnish, depend upon the character of the material upon which they work, that is to say, upon the general preliminary education possessed by the student at the time of his matriculation. This is evidently too often defective, and only a few schools have thus far ventured to establish any standard of preliminary examination which at all approaches in its demands that which is required in England.

The proverb that it does not pay to give a $5,000 education to a $5 boy is clearly of American origin, and sums up a great deal of experience.

You have nineteen portals of entrance to the profession, and have not found it easy to keep them all up to the standard. In America, we have over eighty gates, a number of turn-stiles, and a good deal of the ground is unenclosed common. Many of our physicians are more or less dissatisfied with this state of things and with the results thereof, and every year, in some States, efforts are made to secure legislation which it is supposed will protect the interests of the

profession, though those who advocate such legislation are usually prudent enough to claim as their only motive a desire for the protection of the public.

Now, how does this free trade in medicine and the low standard of qualification, or no standard at all required by law, affect practitioners as individuals? To answer this we must divide the profession into several classes. In the first place, in all our cities, great and small, there is a large class of physicians who are as well educated and as thoroughly competent to practice their art, as can be found in the world. They have studied both at home and abroad, have had extensive clinical training, are always supplied with the latest and best medical literature and the most improved instruments, and many of them are connected with hospitals and medical schools. Among them are found the majority of our writers and teachers, and the successful men are the survivors of a struggle in which there has been keen and incessant competition. These physicians, whose positions are fairly assured, and who, as a rule, have all the practice they desire, are not usually active leaders in movements to secure medical legislation, although they passively assent to such efforts, or, at least, do not oppose them; and their names may sometimes be found appended to memorials urging such legislation. They are clear-headed, shrewd, "practical" men, who know that their business interests are not specially injured by quacks and ignoramuses, rather the contrary, in fact, for they are called on to repair the damage done by the quack to people who have more money than brains; and they are not inclined to risk the fate of the Mexican donkey who died of "*congojas agenas*," that is, "of other people's troubles."

Then there is another large class of honest, hard-working practitioners who rely more on what they call experience and common-sense than on book-learning. Many of these have obtained assured positions of respectability and usefulness, and are comparatively indifferent to medical legislation, so far as their own interests are concerned. Others, however, who are not so successful, feel the competition of the local herb doctor or of the travelling quack more keenly, and have more decided views about the importance of diplomas. Among these are the young men who have not yet acquired local fame, and who are apt to become very indignant over the doings of some charlatan in the neighborhood, or of some druggist who prescribes over his counter. These last are usually quite clear in their minds that the State ought to interfere and prevent injury to the health of the people.

I have known two unsuccessful physicians who finally abandoned practice, and who gave as a reason of their failure — one that "he did not know enough," and the other, that "he had not the manners and tact which would inspire confidence in his patients"; but such frank-speaking men are rare.

Thus far, as a rule, the efforts which have been made to secure legislation upon medical matters in America have come from the profession itself, and have been chiefly urged and recommended by physicians. The general public, and even the educated public, has shown very little interest in the matter. It does not demand protection against ignorance, but entrusts the care of its health, and the lives of those who are nearest and dearest to it to almost any one who announces himself as prepared to take charge of them. The number of those who profess to practice medicine in the United States, and are not qualified to do so, is undoubtedly large, though by no means so large as one might suppose after listening to the impassioned eloquence which is duly aired every year upon the subject. There are some advertising charlatans and travelling quacks occasionally to be met with, but they are rare.

The most rigid tests of qualification, in our profession in the United States, are those required of candidates for admission into the medical departments of the army and navy. The standard established for these is about the same as that for the corresponding corps of the English army and navy; and of the candidates who apply, from seventy to eighty per cent. are rejected.

Certainly, we must admit that this percentage indicates an unsatisfactory state of things. But what evidence have we as to its results upon the health and life of the people? What shall we take as the measure of the difference of skill in physicians? The death-rate? If we compare the death-rate of the United States with those of other civilized countries, we find that it is as low as any with the exception of Sweden. Does a low death-rate mean better sanitary condition or more skill among the doctors? For the last twenty years the death-rate has been diminishing in England; the average amount of life for each person here has been increased, but I observe that the sanitarians claim this as proof of the value and importance of their efforts, and that nothing is said about its being in any way due to increase in medical skill or to improvements in medical science. Evidently this test is not a convincing one. Almost the only matter in which figures seem to demonstrate the importance of superior medical education and skill is in the statistics of deaths due to childbirth and of the results of surgical operations.

The proportion of deaths from childbirth to the number of births is decidedly greater in the rural districts than in large cities, and among the colored than among the white population. If this difference were found only in the United States statistics, it might be accounted for by the differences in the trustworthiness of the sources from which the data are derived; but we find similar differences in England, and we must admit that these are probably largely due to the fact that in cities labor cases receive more prompt and efficient professional care than they do in the country. I need hardly call your attention to the results of antiseptic surgery, or of modern abdominal surgery, as compared with those of twenty-five years ago. Here there can be no question as to the improvement. It is well to remember in this connection that whatever undue prolongation of disease or unnecessary mortality is due to want of skilled medical treatment occurs mainly among the wage-earners, the farmers, mechanics, salesmen, needlewomen, etc., and not among the rich, nor yet among the very poor.

Now, seeing that really efficacious legislation with regard to medical education or to the practice of medicine must, like all efficacious legislation, be substantially in accord with public opinion, since it is impossible to continue to punish for any length of time that which public opinion does not condemn; and as the great mass of the people of the United States have not as yet had such evidence as they can understand, and would thoroughly convince them that it is to their interest to suppress quackery, it follows that it is neces-

sary to go slowly and to allow such evidence to accumulate.

To me it seems that the most important of the first steps to be taken in this direction is one which has already been taken in Great Britain— namely, the requirement that every death in the community shall be registered, and that in such registration satisfactory evidence shall be given as to the cause of death, sufficient at least to prove that such cause is what is known as a natural cause, that is, that it is not due to crime.

When it is admitted that one of the duties of government is to provide for such registration, both in the interests of life and to secure the rights of property, it follows, necessarily, that those persons whose certificates as to the cause of death are to be accepted as satisfactory evidence that there has been no foul play, must present evidence that they are properly qualified to make such certificates. The principle is precisely the same as that which induces a government to provide for the examination of the medical men whom it employs in its army and navy.

So far as the art of medicine is concerned, the demand has much, though by no means all, to do with regulating the quantity and quality of the supply; and there are few localities in the United States where the qualifications of the medical man are not fully up to the standard which the community is able to appreciate and is willing to pay for. In the natural order of things suffering and death are the remedies for ignorance, weakness, and vice, and the means of preventing the transmission of these characteristics to offspring. These remedies, though effectual are drastic, and we do our best to avoid them, but perhaps it is well that the penalties cannot be done away with altogether.

The rules regulating the practice of medicine in the United States are all State laws. If we were to judge only from what may be found in the statute books, assuming that all the laws contained therein are duly enforced, we should find that nearly two-thirds of the States have laws ostensibly regulating the practice of medicine within their borders. As a matter of fact, however, in over half the States which have laws on this subject no attempt is made to enforce them, and in almost all of them the possession of a diploma, no matter from what source derived, is all that is required.

Of the various methods which have been tried in different States to insure by law that physicians shall be properly qualified, I will call your attention to two which are of special interest.

The first is that of Alabama, the principle of which is to organize the whole medical profession of the State, and use it as the means of regulating the qualifications of practitioners and of caring for the public health. The Medical Society of the State of Alabama with its branches, the county medical societies, thus forms a part of the machinery of the Government; it appoints boards of medical examiners, selects State and county sanitary officials, supervises the registration of vital statistics, the administration of quarantine, etc.,—in short, it is the State Board of Health, and the county branches are the county boards of health.

In this State the possession of a diploma does not give the right to practice, it simply enables the owner to go before the examining board. The examinations before the County Board are partly in writing, and are subject to review by the State Board, which has in some instances publicly condemned the local examinations as not sufficient.

This system has now been in operation nine years, and has gradually been consolidated and improved by educating local boards, and getting all physicians interested in it, until it is now working fairly well. Much remains to be done, and it is too soon to predict results; at present the success of the system is largely due to the wisdom and energy of one man, who has given his whole time and labor to the work, and it remains to be seen whether the machine which he has built will work well without him.

The second system to which I will call your attention, is that of the State of Illinois, which was commenced in 1877, or about the same time as that of Alabama.

In Illinois any one who presents a diploma, or license to practice, from a legally chartered medical institution in good standing, is entitled to practice, and the State Board of Health is to decide as to what shall constitute "good standing." The Board of Health also examines all persons who do not possess satisfactory diplomas, and who nevertheless wish to practice in this State.

One of the greatest practical difficulties in the way of providing any system of State examinations in medicine in the United States, is that public opinion will not support any law which can be supposed to condemn or in any way to injure homœopathic and eclectic practitioners or their schools, and hence any proposed law relating to medicine, or to the organization of State boards of health, which does not recognize the existence of these sects will, in many States, at all events, meet with enough opposition to defeat it. In Illinois this difficulty was surmounted by the arrangement, that of the five physicians on the Board, one should be homœopathic and one eclectic. The Kansas law, passed last year, goes further in this direction, and provides that appointments must be so made that no school of medicine shall ever furnish a majority of the members of the Board. Much to the surprise of many, the Illinois plan has worked very well — there has been no quarrelling in the Board —and the homœopathic and eclectic members seem to have upheld quite as high a standard of qualification as their fellow members. The results of the work in Illinois have been very good. A large number of ignorant charlatans were forced to leave the State. The requirements of the Board as to what shall constitute a medical college in good standing, have been raised, and it has thus caused improvement in the medical schools, not only of Illinois, but of other States. Moreover, the neighboring States have been stimulated to action, not only by the force of example, but because they received the men who had been driven out of Illinois, and found the accession an unpleasant one.

As in the case of Alabama, it is too soon to judge definitely of the results; and in Illinois, also, the satisfactory working of the system is largely due to one man, the Secretary and executive officer of the Board, who has given his entire time to the work. I do not, by any means, wish you to suppose, however, that I consider this as being a serious objection to this or any other plan, for in the building up of any organization, or the carrying out of any system, much must always depend upon some one man.

The relations of the United States Government to medical education and to the practice of medicine are indirect only, the regulation of these matters by law being part pf the police power which, under the constitution, is reserved exclusively to the individual States. The United States employs physicians in its Indian Department, in the Pension Department, in the Marine Hospital Service, and in the medical departments of the army and navy, and it has power to regulate the practice of medicine in those territories which are not yet organized into States; and also in the District of Columbia; but thus far it has made no use of such power. The qualifications of physicians employed in the army and navy and in the Marine Hospital Service, are determined by examinations made by boards of medical officer sbelonging to those services. The possession of a diploma from a respectable medical college is a pre-requisite for such examination, but beyond this it does not count; that is to say, the examination is the same for the holders of all diplomas, and covers all branches of medicine. But while the relations of the general government to medical education are thus indirect, they have of late years become of very considerable practical importance, and are now exerting much influence upon medical investigations and literature. This is being effected by the museums and libraries which are now being formed under the auspices of the government at Washington, and also, to some extent, by certain special investigations undertaken by the government in the interest of preventive medicine. Of these various agencies one of the most important is the library which has been formed at Washington, under the auspices of the medical department of the army in connection with the Army Medical Museum; both of these institutions being a part of the results of the late civil war. The museum was at first formed to illustrate military medicine and surgery, giving the results primary and secondary, of injuries inflicted by modern weapons of warfare and of the diseases of armies in the field; in which direction the collection is unrivalled in extent and completeness. Gradually its scope has been enlarged to include illustrations of anatomy, development, and all branches of pathology and therapeutics, so that it is fast becoming a museum covering the whole field of medical science. In like manner, the library, which commenced in a collection of those books relating solely or especially to military medicine and surgery, which were required in the compilation of the "Medical and Surgical History of the War," has expanded into a great medical library, which is now one of the best practical working collections of the kind in the world. These collections, then, no longer appertain exclusively, or chiefly to the business of one department, but belong to the whole profession of the United States as a body; and the department which has charge of them is managing them from this point of view. The influence of the library in stimulating research, and upon the quality of medical literature, is already very perceptible, and is destined to increase with advancing years. I think I may also venture to claim that the utility of these collections, and especially of the library, is by no means confined to the medical profession of the United States, for the catalogues and indexes which are being issued in connection with them, are of service to medical writers and teachers all over the world.

As regards investigations into the causes of disease, undertaken at the expense of the general government, only a beginning has as yet been made; but it is sufficient to indicate future possibilities and probabilities. The main importance of the work of the National Board of Health, which was organized in 1879 under the stimulus of the great yellow fever epidemic of the previous year, was due to investigations upon the causes of yellow fever and diphtheria, the relations of soils and of water-supply to certain diseases, etc., investigations of the same general character as those which are being prosecuted under the auspices of the Local Government Board in this country, and of the Imperial Board of Health of Germany. It is true that owing to circumstances which I cannot here explain, the work of the National Board of Health has been stopped; but there is every probability that it will be resumed, with perhaps some change of organization, at no distant day, and I need not dwell upon the vast importance to medical science of organized and systematic work in this direction. Similar investigations have been undertaken by State boards of health, and especially by the State Board of Health of Massachusetts, and the fact that governmental health departments are tending to work in this direction is significant as to future coöperation from such sources.

In this connection should be mentioned the National Museum of Hygiene, which has been formed under the direction of the medical department of the United States Navy, which is now one of the most instructive collections of the kind in the world, and has also connected with it an excellent library and a well-equipped laboratory.

Comparative and experimental pathology is also receiving attention from the Government under the direction of the Department of Agriculture, which is doing some good work in the investigation of the diseases of our domestic animals. Our investigators are, fortunately, not hampered by antivivisection laws, and there is little danger that they ever will be, for though we have our due proportion of fanatics and seekers of notoriety who wish to emulate the British Antis-, their true motives are so well understood that they have little power to do mischief.

Of medical associations in the United States there are several classes. We have a few local societies, analogous to clubs in their organization, which own property in the form of buildings, libraries, etc., are somewhat conservative in their selection of members, and are only to be found in large cities. Of these, the College of Physicians of Philadelphia is the oldest, and has the largest and best library and museum — it will celebrate the hundredth anniversary of its existence next year. In New York the Academy of Medicine, and in Boston the Medical Library Association, are of the same character, and, in general, each large city has a similar society, although as yet they have not become fully anchored and established by the acquisition of property. The second class includes local societies devoted to specialities such as pathology, obstetrics, etc. These also are found only in large cities, and as yet are few in number. Four of them only have published transactions. Corresponding with these are national societies devoted to specialties such as gynæcology, ophthalmology, surgery, pathology and clinical medicine, etc. These societies meet annually, elect their own members, exercising care in the selection, and publish valuable transactions.

Another class is composed of the county medical societies, which strive to include all regular practitioners residing in their precincts. From these are sent delegates who form the State medical societies and the American Medical Association. The mode of organization varies somewhat in the different States, but the representative principle prevails in all. Most of these societies publish transactions, and the American Medical Association now has its journal.

As to the condition of medical science and art in America, it partakes of the general progress, for the press now makes all discoveries the common property of the civilized world. The marked feature of the present epoch is the recent advance in knowledge as to the relations between microörganisms and certain diseases, and the strong stimulus which this has given to preventive medicine. Sanitation is becoming fashionable, and if we may believe some of its votaries, it is a very simple matter to prolong the average lifetime to the scriptural "three score years and ten." All that is necessary is that everything shall be clean, and every person virtuous.

Having learned to distinguish those diseases which can be prevented much more easily and certainly than they can be cured, we may turn them over to the sanitarian, who has his own battles to fight with ignorance and prejudice. If he succeeds, and so far as he succeeds, he will change, in certain respects, the work of the practitioner.

The lives which are saved from cholera and typhoid, from consumption and diphtheria, and from the acute specific diseases, will, at last, be weakened and destroyed in other ways. The work of the physician will not be lessened by preventive medicine, it will simply be required more for older persons, and for another class of diseases. As sanitarians must depend upon practitioners for much of the information which is essential for their work, it follows that if preventive medicine is to become a working power, it will bring the mass of the profession into closer relations with the State than its members have held heretofore. What these relations shall be is one of the most interesting, and, at the same time, one of the most difficult, of the many problems with which we, or our successors, must deal. I have referred to some experiments on this subject which are now being tried in America, where it is much easier to make such trials than it is in an older country hampered with vested interests.

Just at present, in this, as in a number of other things, our tendency is toward centralization, both in the several States and for the whole country, and it is not improbable that we may go far on this road in the future.

I come now to the consideration of the second part of my subject, namely, the direction or manner in which we have reason to hope that medicine will be developed in the United States, and the kind of coöperation which you may reasonably expect to receive from the medical profession of that country.

A marked feature of the present day, in medicine, as in other things, is the tendency to specialization in study and in practice. But this very development of specialties, of increasing minuteness in the division of labor, increases the necessity for coöperation, and in fact tends to create what we may call the specialty of coöperation. Formerly a rifle, or a watch, was made by a single workman. No two instruments were exactly alike, each piece had its own individuality, and was not interchangeable, and the cost of the whole was such as to put it beyond the reach of the multitude. Now, the work on these things is greatly subdivided, one man makes only one small wheel, or spring, or pinion, and another another, each doing his work according to a uniform pattern, rapidly, perfectly, and at comparatively small cost.

But, in addition to the workmen who make the individual parts, it is now necessary to have one person specially skilled in making drawings and preparing patterns, another to assemble the completed parts, and a third, to test the whole after it has been put together. As the centrifugal force increases, the centripetal power must also increase.

In one sense medicine, as we have it to day, is the result of coöperation, not of deliberate, centrally planned and direct coöperation, but of natural selection from results produced by many men, often working at cross purposes, and, therefore, wasting much energy, but nevertheless working, though blindly, to a common end. And it is safe to predict that in the future much of the best work will be done in the same way, by individual effort inspired by the love of science, by personal ambition, etc. But the results obtained in this way come slowly, and some things that we want can hardly be obtained by individual effort, even if we were willing to wait, hence we must look to organization for help.

This is an age of machinery, of exchanges, of corporations, for all these correspond to one and the same fundamental idea. Men make machines to do what the individual cannot do, and they make them not only of brass and iron, but of men, for such an obvious source of power to the man or men who can master the combination is not likely to be overlooked. One result of such organization is seen in our encyclopedic works on medicine, whether these be called dictionaries or handbooks; another in the great medical journals; another in associations which seek to wield political influence; another in the comparatively recent attempt at collective investigation of disease. With these may be classed also the attempts of Government departments to make scientific investigations, to collect libraries and museums, to do things which require long continuity of effort on a definite plan in order to produce the best results.

And it is by the combination of all these, with the efforts of individual workers, that substantial advance and improvement are to be effected.

In this broader view of coöperation, it is interesting to consider those fields of labor to which comparatively few physicians can devote themselves, because of want of time and opportunity, but whose proper working is, nevertheless, of the greatest importance to the practitioner.

One of these is experimental laboratory work, and in this direction, the prospect of valuable contributions from America is now exceedingly good. Some of the wisest of our most wealthy men have shown their appreciation of the responsibilities which riches entail on their possessors by seeking new channels through which to benefit their fellowmen. While the old and well-known methods of endowing hospitals and charitable institutions are not neglected, there is apparent an increasing tendency to endeavor to promote the advancement of knowledge, and especially of such knowledge as tends to the mitigation of suffering and the improvement of the race, to furnish means for the investigation

of disease, to provide laboratories, and to endow medical schools, and thus place them beyond the reach of the temptations and difficulties which must always exist when such schools are dependent upon the fees of students, and are, therefore, practically commercial manufacturing establishments.

As illustrations of this tendency, I may mention the bequest of £1,400,000 by Johns Hopkins to endow, in the city of Baltimore, a university and a hospital, of which the medical department is to be a special feature, to be provided with the best laboratory and other facilities for original investigation, as well as for teaching; the gift of Mr. Carnegie to the Bellevue Hospital Medical School of New York, in the shape of a well-equipped pathological laboratory; the presentation by Mr. Vanderbilt, and members of his family, to the College of Physicians of New York, of £200,000, to provide for that school new buildings and clinics having the best means of teaching and research, and the endowment by an unknown donor, of a laboratory for the University Medical College of New York, with the sum of £20,000.

Last year, in his retiring address as President of the New York Academy of Medicine, Dr. Fordyce Barker referred to this tendency to regard wealth as a trust to be used for the benefit of humanity, and, after sketching the requirements of the Academy on a scale which would require an endowment of at least a million of dollars, predicted that such an endowment would be furnished by wealthy citizens of the city. I believe that he was right, and that his prediction will become history.

As the class of men who have wealth, leisure, and knowledge becomes greater, there comes an ever-increasing demand, not only for the best medical skill, for the most expert practitioner, but also for exhaustive research in every direction which promises to furnish new means for the prevention or relief of suffering, and for warding off, as long as possible, the inevitable end; and hence there is little reason to doubt that the examples I have named will be followed by others in the near future. With such opportunities, and under such conditions and influences, the stimulus to the young and ambitious worker is strong; we have abundance of material of this kind upon which the process of natural selection can operate, and there is little reason to doubt that the result will be substantial and valuable contributions to physiology, pathology, and therapeutics.

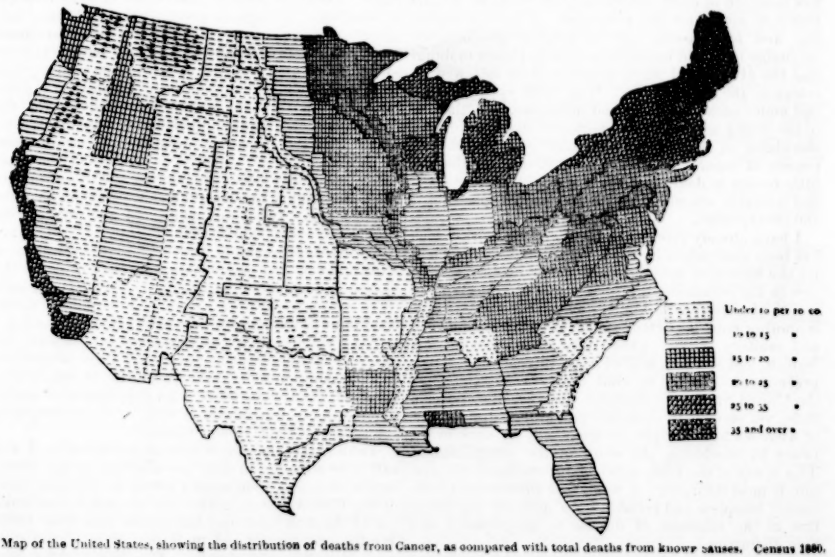
I have already referred to some of the work which has been undertaken by the United States Government for the benefit of medicine and of the medical profession in the formation of a library, and the providing of means of assistance in bibliographical research. There is another most important means of advancing medical and sanitary science which only a Government can furnish, and in which field of work England now stands preëminent — I refer to vital statistics. In this field, the United States Government has thus far done but little, yet enough to show the great interest and value of what we have a right to hope will be done in the future by combining the work of the several States. This is one of the fields in which international coöperation is most desirable; it alone can furnish data sufficiently complete and reliable for a scientific consideration of the relations of disease to geographical and race distinctions.

Geographical pathology is a very old branch of medicine, as old, at least, as Hippocrates, whose treatise on airs, waters, and places is justly famous. Permit me to remind you of its opening clauses: "Whoever wishes to investigate medicine properly should proceed to consider the seasons of the year, and what effects each of them produces, the winds, the qualities of the waters, the situation and exposure of the city, the character of the ground, and the mode of life of the inhabitants." Then, says the wise old Greek, "From these things he must proceed to investigate everything else."

There is a breadth of view in that last sentence which is particularly satisfactory. Since the days of Hippocrates, there has accumulated a vast amount of literature relating to the supposed connection between the topographical peculiarities of different cities and countries, and the diseases which prevail in them, but when the books and essays, which come under the heading of "Medical Topography," are examined, it will be found that the topographical part is much more complete than the medical — which last is mainly confined to the consideration of malarial diseases, and is vague and indefinite with regard to their relative prevalence.

Much the larger part of our really valuable information on this subject has been obtained within the last twenty-five years, as Professor Hirsch points out in the preface to the recent edition of his very valuable handbook of geographical and historical pathology, and while the contributions of the United States to this branch of medical science have been already important, I hope to be able to show you that they are probably destined to be of steadily-increasing importance in the future. Considered, as a body, the opportunities of the medical profession of the United States for the study of the manifold influences which can cause, modify, or prevent disease, are in some respects unequalled. As regards peculiarities of climate, soil, altitude, etc., the country is so large as to afford almost every variety of combination, so that nature may be said to be making a series of experiments, on a grand scale, upon the mass of humanity which is so rapidly increasing in the new world. Especially is this the case with regard to the problems of heredity as connected with the mysterious relations of certain forms of disease to race. America is at present the great mixing bowl into which are pouring streams of human life from origins the most diverse, from regions the most remote. Black and white, red and yellow, long skulls and short skulls, Celt, Teuton, and Slav, are being brought together under similar conditions of climate, food, and occupation, thus permitting of the comparison and study of the different effects, if such exist, which result from variations in parentage under conditions of exposure to the same causes of disease.

For a little time, a generation or two at least, the different streams remain pure, then there is more or less mingling, in some cases very little, in others very intimate, but always there is an opportunity of studying the races separately, as well as of investigating the results of their various mixtures.



To illustrate the possibilities in this direction, I will call your attention to some peculiarities in the distribution of deaths from certain causes in different parts of the United States, and for this purpose I shall make use of the data from our last census, taken in 1880. We have no general and uniform system of registration of births and deaths. The larger cities, and

about half a dozen States, have such a system, but for much the larger portion of the country the only means which we have for determining differences in amount or causes of mortality in different localities is through the census, which is taken once in ten years. The data thus obtained with regard to deaths are imperfect, because when these are collected, only at the end of the year, about thirty per cent. of the deaths are unrecorded; and they are inaccurate, because the reports of the causes of death are not furnished by persons competent to give reliable information with regard to them. Nevertheless, these data are the best that we have, and although for a large part of the country they do not give us the actual number of deaths from any cause or set of causes, they do furnish some interesting information with regard to the relative prevalence and importance of certain causes, and suggest questions and lines for future investigation, although they do not furnish definite and scientific answers.

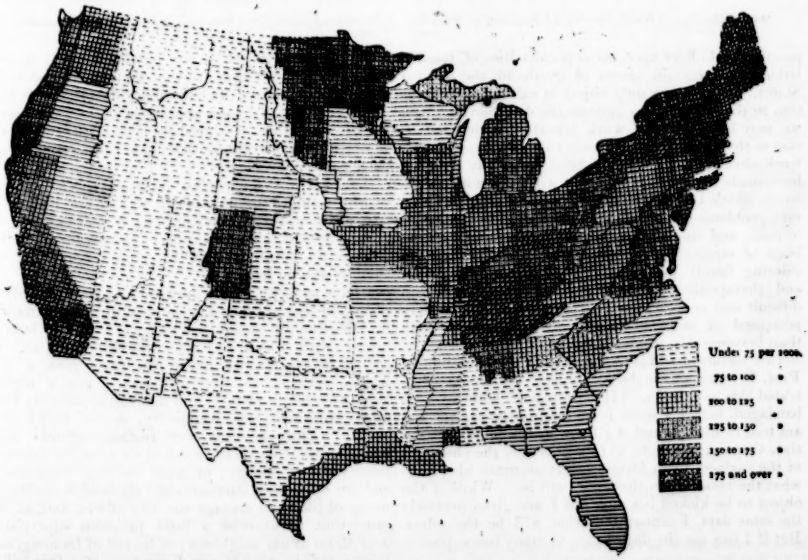
Take, for instance, this map of the United States upon which, by varying shades of color, is shown the proportion of deaths reported as due to cancer, as compared with the reported deaths from all causes. Cancer, using the term in its broadest sense, is a disease which seems to be gradually increasing in frequency among civilized nations, and, possibly, to have a tendency to increase with the advance of civilization.

In England and Wales the proportion of deaths from this cause seems to have nearly doubled within the last twenty-six years, and a similar rate of increase can be made out in certain parts of America. How far this increase is a real one, and how far it is due simply to improvement in diagnosis, is a question yet unanswered.

The mortality from cancer in the United States is proportionately greatest in the New England States, somewhat less so in New York and Pennsylvania, and it causes the least proportion of deaths in the Mississippi Valley and the South generally. The proportion of deaths from cancer in the United States is somewhat greater than it is in England; but it is not possible to make any accurate comparisons in this respect. Now why are the shades on this map so dark in the northeast and so light in the south? In the first place, cancer is a disease the mortality from which steadily increases with advanced age, as you may see from this diagram. Hence, cancer causes a higher proportion of mortality in those localities which have the greatest proportion of population living at advanced ages, and in the United States these localities are the New England States, as you will see by this map. One deduction from this which may perhaps not have occurred to all of you, is that a large proportion of deaths from cancer indicates, to a certain extent, that the locality in which it occurs is a healthy and long-settled one, since it has probably a relatively large proportion of inhabitants, and especially females of an advanced age. But another explanation of the peculiar shading of the cancer map is found in the relations of race to the tendency to death from this disease. The proportion of annual deaths from cancer per hundred thousand living population was, in round numbers, twenty-eight for the whites, and thirteen for the colored. That is to say, cancer is more than twice as prevalent among whites as it is among colored in the same localities, for these figures apply only to the South. On the other hand, cancer appears to cause a greater proportion of deaths in persons of Irish and German parentage, than it does among the rest of the white population, the indications being that between the ages of fifteen and sixty-five, the Germans are especially liable to cancer; more so than the Irish,

Map of the United States, showing the distribution of deaths from Cancer, as compared with total deaths from known causes. Census 1880.

and decidedly more so than the average white population. Now when we remember that the greater part of the colored population is in the South, and the greater part of the Irish and German population is in the North, we have another reason for the differences in mortality caused by this disease in the two sections.

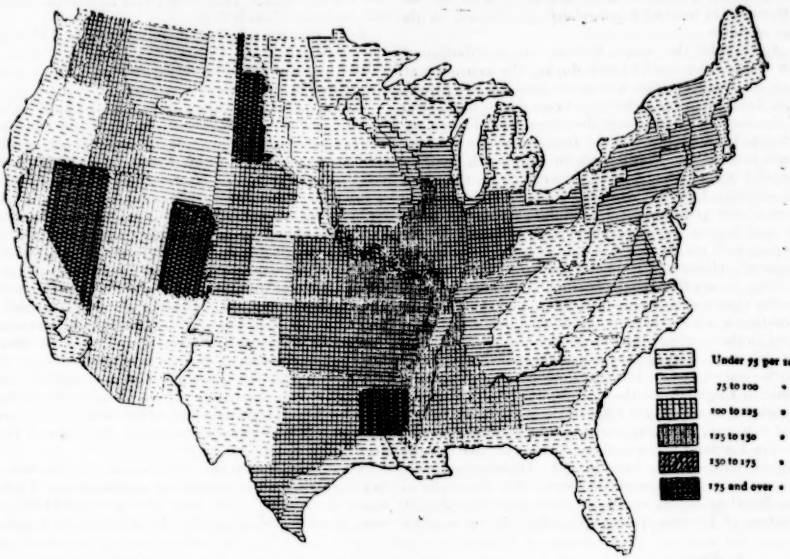


Again, take the maps, howing the distribution of the deaths from scarlet fever during the census year. You see that this also was most fatal in the North, and, here again the influence of race comes in, because in the negro race the mortality from this disease appears to be very low. This disease has always been much rarer in the South than in the North, and the contrast was much stronger in former years than it is at present: but this cannot be explained solely, or even to any great extent, by difference of temperature because scarlet fever has often been epidemic in the tropics, and, on the other hand, in many localities in temperate climates it is among the rarest of diseases.

Here is another map showing the distribution of deaths reported as due to diphtheria during the year. Diphtheria is a disease which has been unusually prevalent in the northern portion of the United States for several years. During the census year it caused 2,374 deaths out of every 100,000 deaths from all causes, while in England, for the year 1880, the deaths from diphtheria were 532 per 100,000 deaths from all causes, that is to say, the comparative mortality from this disease in England was less than one-fourth that of the United States for the same period. Diphtheria, again, is essentially a disease of the North but especially of the Northwest. It causes an excessive mortality in children of German parentage, sufficiently so to show that here again the influence of race comes into the problem, although, probably, only indirectly, that is to say, it is probable that it is the habits of a peculiar class of people which favors the propagation of the disease rather than any physical peculiarities in the structure of their bodies.

Two more illustrations of the geographical distribution of disease in the United States may be of interest in this connection. The first is that of consumption, the second of pneumonia

Consumption is a vague term, and, as used in the census, no doubt includes many cases which were not true tubercular phthisis. It is reported as causing twelve per cent. of all the deaths, or more than any other single cause. In England and Wales, in 1880, it caused a little over nine per cent. of all the deaths. Such wholesale ratios are, however, of little interest or value. There are very great differences in the liability to this disease in different parts of the United States, as the map makes sufficiently evident, and it is from a study of the causes of these differences in the data derived from large masses of people, combined with clinical histories and experimental laboratory work, that we have good reason to hope to obtain knowledge, not only of the causes of this disease, but of better methods of prevention and treatment than are now at our command. It causes a greater mortality among the Irish than in other white races, and, perhaps a greater mortality among the colored than among the white.



Next to consumption, pneumonia is reported as causing the greatest number of deaths in the United States during the census year, giving a ratio of 8.3 per cent. of all deaths, as against 4.8 per cent. in England

Map of the United States, showing the distribution of deaths from Consumption, as compared with total deaths from known causes. Census of 1880.

and Wales in 1880. Here, again, the local distribution of deaths is interesting, and the contrast between the map of consumption and that of pneumonia is very striking. Here, again, we find that race peculiarity is an important factor in the problem, the proportion of deaths from pneumonia among the colored being much greater than it is among the white.

I have elsewhere commented more fully than it is

Map of the United States, showing the distribution of deaths from Pneumonia as compared with total deaths from known causes. Census of 1880.

possible to do here upon these peculiarities of the distribution of certain causes of deaths in the United States.[3] In fact, my only object in calling your attention to the subject is to indicate the direction in which we may hope for good work hereafter, which indication is the chief, if not the only valuable result of the work already done. In the brief comments which I have made upon these maps you will have noticed the stress which I have laid upon race peculiarities. These race problems are simply problems of heredity taken in mass, and there is no need to urge upon an assemblage of medical practitioners the importance of considering family peculiarities in diagnosis, prognosis, and therapeutics. That the questions involved are difficult and complicated is true, but we are already possessed of more knowledge with regard to them than is commonly supposed.

In a lecture on "Life" delivered a few months ago, Prof. Brookes, of the Johns Hopkins University, illustrated this as follows: "If I am placed, with my eyes bandaged, before a stone lying free on the surface and am told to kick it, and if I know at the same time the size, shape, and weight of the stone and the character of the surface, I can form a pretty accurate idea as to what the result upon the stone will be. While if the object to be kicked is a dog, and I am given precisely the same data, I cannot tell what will be the effect. But if I can see the dog, I can, in many cases, predict pretty accurately. If he is a bulldog, he will do one thing; if he is a Gordon setter, he will do another." And, in like manner, the old family doctor knows that when a particular disease appears in his neighborhood, he may expect to see it produce in one family convulsions, in another collapse, and, in a third, little or no danger or inconvenience."

This kind of knowledge is, however, at present mainly confined to individuals, it has not become a part of the world's knowledge: it is not defined; in other words, it is not scientific. To make it so, is the work of the future, and in this work I hope that we shall be able to help you.

I have spoken to little purpose if I have failed to show you that there is a great deal of human nature in American physicians, and that it is a kind of human nature with which you are tolerably familiar. It should be so, for we are of the same race, a race which, perhaps, as Emerson says, "sets a higher value on wealth, victory, and material superiority than other men, has less tranquility, is less easily contented." Our ancestors were restless, fighters, free-booters, and from these ancestors we have the common inheritance of energy; of what *we* call "firmness," and our opponents unreasonable, pig-headed, stubbornness; of liking to manage our own affairs, and, at the same time to exercise a little judicious supervision over those of our neighbors; of hatred of humbug, and lying; and, in spite of our discontent, of a firm belief that our wives and children, habits, houses, mode of

[3] See report on Mortality and Vital Statistics of the United States as returned at the tenth census, 2 vols., 4to, Washington, 1885–1886.

business, and of treating disease are, on the whole, better than those of any other people under the sun.

Privately, and between ourselves, we grumble and declare that the country and profession are going to the dogs — nay, we must do so, or we should not be of true English blood, but there is no need for me to tell you that these are only "growing pains," and not symptoms of progressive ataxy.

While we must consider the difficulties in the way of the improvement of the science and art of medicine, difficulties due to ignorance, to indolence, to conflict of interests, and to the eternal fitness of things, the existence of such difficulties is not a matter to be bemoaned and lamented over. These obstacles are the spice of life, the incentives to action, the source of some of the greatest pleasures which it is given to man to experience.

The child, spending a happy hour with its new puzzle, is a type of the scientific investigator. The naturalist who objected to the statement that this is a miserable world which it is well to be soon done with, on the ground that there are still many species of rhizopods which he had not examined and classified, is another type. On the ethical and sociological side, the matter is summed up in Ruskin's aphorism, that "Fools were made that wise men may take care of them."

It is surely not without cause that there has been given to us this restless spirit of inquisitiveness, this desire to compass the heavens and the earth, this raging infinite thirst for knowledge, it is the outcome of brain training and natural selection for thousands and tens of thousands of years.

We are in a period of the world's history characterized by material prosperity, by increase of populations, by tendencies to uniformity, to the making of individuals of small account. According to the Swiss philosopher, Alphonse de Candolle, this is to last a thousand years or so, after which the pendulum will swing the other way, and there will follow a long period of diminution and separation of peoples, and of decadence.

Against that decay of nations we know of but one remedy, and that is increase of knowledge and of wisdom. And this increase must be in *our* knowledge, in the world's wisdom, and not merely in that of John, or Fritz, or Claude.

As each man has special opportunities and duties, if he can only recognize them, so it is with guilds, with professions, and with nations.

I have tried to indicate to you some of these opportunities which are presenting themselves to my colleagues, your brothers, in the lands beyond the sea, and I hope that I shall not be considered rash, or vainglorious in saying that I believe they will so use those opportunities as to return compound interest for what they have received from the storehouse of our common inheritance. Force changes form and place, the stored energy of the soil of our plains and valleys has been coming here in the form of meat and grain, has appeared in muscle and brain, and in a hundred other shapes, but none has been destroyed; our loss has been your gain, and in our turn we have received full and fair exchange.

It is our part now to remember that there are not two springs in the year, there are not two periods of youth abounding in energy and desire, or of manhood's strength and self-poise, in the life of any man or of any nation, and for us, as for those who have been before us, the Kanuri proverb holds true, "*Kabu datsia, kargum bago*"— The days being finished, there is no more medicine.

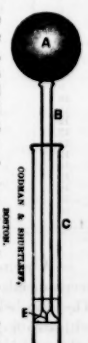
WOLPERT'S AIR-TESTER.



BY S. W. ABBOTT, M.D.,
Secretary, State Board of Health.

For the purpose of ascertaining the quality of the air of inhabited apartments, an instrument is very much needed, which shall combine in itself the following characteristics: convenient form and size, portability, and facility of application or use. Strict accuracy, while desirable, is not absolutely essential.

The thermometer has been in use for many years, and shows the temperature of an apartment at a glance, while the barometer shows the density of the air, the hygrometer its moisture, and the aneurometer the velocity of air-currents in ventilating shafts or ducts. All of these conditions, measured by such apparatus and properly modified, are essential to the comfort of persons occupying such apartments as school-rooms, work-shops, public institutions, lecture-rooms, railway-cars, mines, etc., etc.

On the other hand, when the actual health of the occupant is considered, there is no more important condition than the quality of the air itself in any given apartment, and yet, for the determination of such quality, a convenient, portable instrument is not often found. Those which have hitherto been employed, while possessing the merit of tolerable accuracy, are inconvenient, clumsy, and too expensive for ordinary use.

Recognizing the fact that thus far, no better test of the pollution of air by the products of respiration and combustion has been found than the per cent. of the carbonic acid which it contains (the normal amount in pure out-door air being from 3 to 5 parts per 10,000), the little instrument known as Wolpert's air-tester, described in a recent article by that author,[1] answers the above purpose fairly well when strict accuracy is not required. Some such instrument ought to be found, and used in every school-room, work-shop, or other apartment liable to vitiation of its air.

This little instrument consists of a simple rubber bulb (A), of a capacity of 28 cubic centimeters, a glass outlet-tube (B), with a constriction near its extremity (E). A glass test-tube 12 centimeters in length (C), and 12 millimeters in diameter, has a horizontal mark near the bottom, indicating the point to which it must be filled with perfectly clear lime-water, to contain 3 cubic centimeters. The bottom of the tube is whitened, and has a black mark stamped upon it (D). A small wooden stand, a brush or swab, a vial of vinegar for cleaning the tube, and a bottle of clear lime-water, completes the outfit.

In order to use the instrument, the lime-water (saturated solution) should be poured into the test-tube till it reaches the horizontal mark. Press down the bulb with the thumb, so as to expel the air within it as completely as possible, and allow it to fill

[1] Einfache Prüfung der Luftreinheit in Wohnräumen, von Dr. Wolpert, Prof. in Kaiserslautern. Centralblatt für Allgemeine Gesundheitspflege, Vol. II, p. 231.

with the air of the apartment, insert the small tube into the lime-water nearly to the bottom, and again expel the air with moderate rapidity, so that the bubbles may rise nearly to the top of the tube, but do not overflow, taking care to continue the pressure of the thumb till the small tube is removed from the lime-water. Repeat this process until the mark upon the bottom of the test-tube is obscured by the opacity produced by the reaction of the carbonic acid upon the lime-water, the observer looking downwards through the lime-water, from the top of the test-tube.

With very foul air, it is necessary to examine the mark after filling and discharging the bulb a few times only; with good air, it must be filled twenty-five times and upwards.

The bulb represented in the cut is made a little larger than the required capacity, since a small amount of residual air usually remains in the bulb and cannot be expelled without great care.

After each observation, the test-tube must be washed out and wiped dry. If a white incrustation forms upon the tube, it may be easily removed with a little vinegar, after which the tube should be thoroughly washed with pure water and dried.

If the mark becomes obscured after filling the bulb ten or fifteen times only, the air of an apartment is unfit for continuous respiration.

In a sick-chamber, the air should be so pure that the turbidity of the lime-water will not render the mark invisible until thirty or forty fillings are made.

The instrument should be used by daylight, over a white ground, as a sheet of writing-paper, and care should be taken not to vitiate the result by the observer's own breath.

The following approximate table is taken from the article by Professor Wolpert, the first column representing the number of fillings of the bulb, and the second column the parts per 10,000 of carbonic acid in a given sample of air.

Number of Fillings.	Carbonic Acid per 10,000.	Number of Fillings.	Carbonic Acid per 10,000.	Number of Fillings.	Carbonic Acid per 10,000.
1	200.	21	9.5	41	4.9
2	100.	22	9.1	42	4.8

17	12.	37	5.4	57	3.5
18	11.	38	5.3	58	3.5
19	10.5	39	5.1	59	3.4
20	10.	40	5.	60	3.3

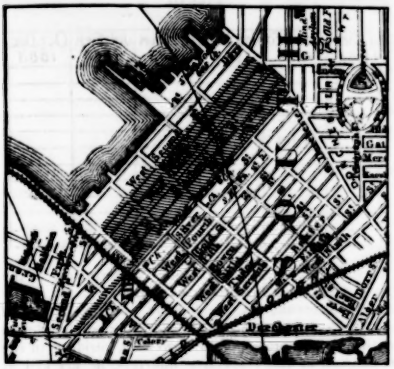
— A writer in the *American Practitioner and News* recommends the following treatment for freckles: The skin being washed and dried is put on the stretch with two fingers of the left hand, and a drop of carbolic acid is applied exactly over the patch. When it dries the operation is completed. The skin becomes white, and the slight sensation of burning disappears in a few minutes.

ABUSE OF MEDICAL CHARITY. — A REMEDY APPLIED IN 3000 CASES OF OUT-DOOR PATIENTS: RESULTS.[1]

BY FREDERICK F. DOGGETT, A.B., M.D.,
District Physician to the Boston Dispensary.

IT is proposed to devote the remainder of this paper to the statement, working and results of a simple plan for preventing abuse of medical charity, adopted by the writer early in 1883, and continued since then in district dispensary practice.

The plan was briefly as follows :— in doubtful cases to ask — 1st, the number of persons in the family; 2d, the united wages or total source of income; 3d, as to the permanency of it, and as to any debts due from previous lack of work; 4th, as to the rent paid. Afterwards, as a supplement to this, to confirm the answers by statements of neighbors. Next, to note the unworthy families.



If, in the writer's judgment, on pressing the above questions, the family was unworthy, free treatment was refused except in urgent cases. A family of seven or eight persons, with an income of $30 to $40 per month, was always treated. Not so a family of three persons with an income of $60 to $70. All the circumstances were considered, such as the permanency of income, previous lack of work, or sickness. In cases of refusal to answer questions like the above, the case was judged unworthy. This state of affairs was not infrequent. It must be admitted that that is a lenient judgment which rests on the statements of the defendent, and that in a plan of this kind there is small chance of injustice in the distribution of medical charity — at least so far as the receiver is concerned.

The above questions, in the experience of the writer, could be asked and answered in less than a minute, which is not an unreasonable time to take when it is remembered that it was only at first that many such cases were met with; for apparently, when it was learned that they were likely to be subject to an investigation, such cases became scarce. In this way, the writer believes that there was in the end a saving of time and trouble. This is also borne out by referring to the table, No. I, where we can see that in October, November and December, 1882, the number of cases from the pay-district was much in excess of those coming in the corresponding months of the next year.

The part of Boston in question is that part of South Boston, bounded by portions of Dorchester Avenue, Broadway, and Dorchester Street, and the water of Boston Harbor. (See map.) The shaded portion represents the part of this territory occupied by comparatively well-to-do people, such as mechanics, clerks, shopkeepers, etc. For the most part, these people pay their physician's bills, and are able to do so, with some manifest exceptions. Rents range from $10 per month and upwards. Many own the houses they live in.

The rest of the territory — the unshaded part — is bounded by portions of Second Street, B Street, Athens Street (including both sides), Dorchester Avenue, the water, and a part of Dorchester Street. It is occupied by people of small means, for the most part day laborers, with a few fishermen, junkmen, etc. Rents range from $4 a month to $10 or $12, and as this is the region of large families, there is more or less crowding. It is seldom that families will be found in this district able to pay a full physician's bill.

[1] Concluded from page 106.

For convenience, the former territory will be spoken of as the "pay-district;" the latter as the "charity-district." The time covered in the calculations of Table I, and Chart I, was from October 1, 1882, to October 1, 1885. The number of cases treated in these three years was 2,926; of this number, 2,224 resided in the charity-district; 702 in the pay-district.

In order that the working of the scheme may be shown with its results, the three-years' time has been divided into quarterly intervals. The number of cases treated in each quarter has been reckoned. Further, the cases coming from the pay-district and charity-district, respectively, as above described, have been estimated, and the per cent. in each to the total number. (See Table I.)

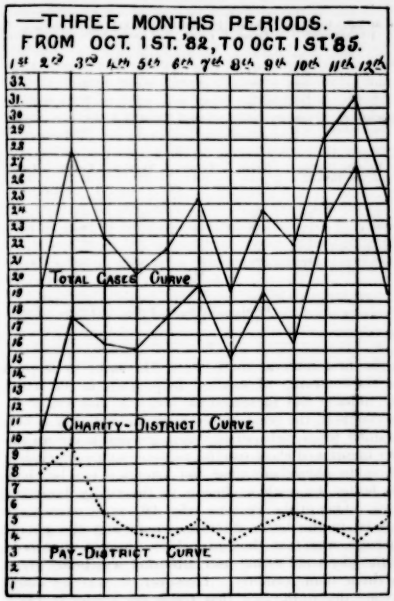


TABLE I.

Time of Experiment.	Total Cases.	Pay-Dist. Cases.	Ch'y Dist. Cases.	% P. D. Cases.	% C. D. Cases.

The principal fact that Table I illustrates — namely, the rapid falling off in the number of cases from the pay-district after March 1, 1883, the beginning of active application of the scheme — can be shown still plainer in the chart form. (See Chart I.) The three-months' interval, beginning October 1, 1882, are represented by the spaces between the vertical lines, while the horizontal spaces represent units of tens of the number of cases coming during the respective intervals. The upper curve shows the tri-monthly variation in the total number of cases; the middle curve, the same variation in the number of cases from the charity-district; the lower dotted curve, the same for the cases from the pay-district.

Besides the falling off in the pay-district curve after March 1, 1883, it will be noticed that it continues at a low level thereafter, showing how few unworthy cases came after investigation began. On the other hand,

CHART I.

the charity-district curve attains and keeps a higher elevation; the high point attained by this curve in the 10th and 11th quarters, is due to the fact that there was prevalent an epidemic of measles in the poorer part of the district during the winter and spring of 1884 and 1885. Otherwise, this curve would have been more uniform in character. The rise of all the curves during the first six months of the author's service may, perhaps, be due in part to the fact that he, at that time, came a new man into the district, and on that account was more likely to be imposed upon. It is further explained by the fact that it was, no doubt, influenced by the usual rise coming at the advance of winter, as witness also the rises at the winter periods of the 6th and 10th quarters.

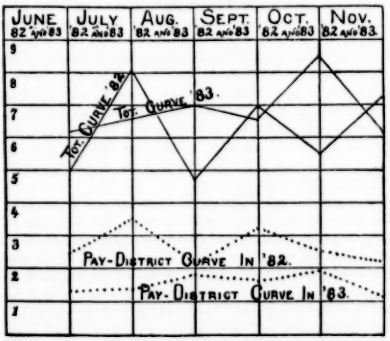
To throw further light on the scheme and its results, a comparison has been made between the number of cases coming from the above-mentioned pay-district, during the six months ending December 1, 1882, and the corresponding six months in the following year — that is, after the scheme had been in use for several months. By the table (Table II) it will be seen that some twenty fewer cases in every hundred of total cases were in the habit of applying for medical charity (also including those cases refused treatment) during the interval from June to November, 1883, than in the same interval in 1882. While in the former interval, 164 persons, in some measure able to pay, got medical charity; in the later interval, under working of the plan, only 95 such persons got such aid. Yet, in the latter interval, instead of there being a smaller number of total cases treated, there was, in reality, an increase of 35 cases. Further, it is to be noted that

TABLE II.

Months Before Experiment.	Total Cases.	Pay-Dist. Cases.	Ch'y Dist. Cases.	% P. D. Cases.	% C. D. Cases.
June, 1882	51	25	26	49.1	50.9
July, 1882	82	35	47	42.7	57.3
August, 1882	45	23	24	48.1	51.9
September, 1882	70	33	37	47.2	52.8
October, 1882	55	26	29	47.2	52.7
November, 1882	73	22	51	30.2	69.8
Months During Experiment.	Total, 378	Total, 164	Total, 214	Total, 43.4	Total, 56.6
June, 1883	62	14	48	22.6	77.4
July, 1883	66	14	52	21.2	78.8
August, 1883	71	17	54	24.	76.
September, 1883	67	16	51	23.9	76.1
October, 1883	85	20	65	23.6	76.4
November, 1883	62	14	48	22.6	77.4
	Total, 413	Total, 95	Total, 318	Total, 22.9	Total, 77.1

in the first interval there were 214 cases in a great degree deserving of medical help, while in the latter, this number had increased to 318. As the writer understands it, the great object of medical charity is best attained when such persons as in general make up the first mentioned class can be to some extent excluded, while the physician's time and attention can be given the better, by such exclusion, to the really deserving class. One of the reasons why 104 more cases were treated in the latter interval, comprising the poorer patients, was, that they probably observed that more of the physician's time and attention was being given to them than formerly. However, it was no doubt further due to the fact that times got harder in 1883, and there was less work; this reason, of course, would apply equally to the pay-district, and yet fewer cases came from this district than in 1882.

CHART II.



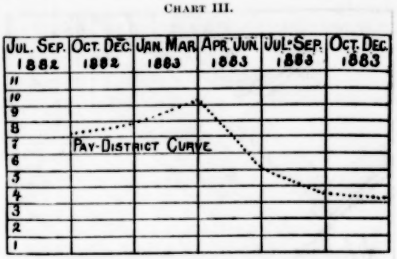


Chart II is supplementary to Table II. In it the horizontal spaces represent units of ten cases, while the vertical columns represent the periods of time. It well illustrates the low pay-district curve in 1883 as compared with that of 1882 — before inquiries were made. It further shows that contemporaneously with this lowering the total number of cases had increased, as can be seen by comparing the total curve for 1883 with that of 1882.

CHART III.

To show in the simplest manner the working of the plan, Chart III has been constructed; six, three monthly intervals, are formed by the time between July, 1882, and December, 1883 — a period of eighteen months. The number of cases treated, residing in the pay-district, in the respective quarters, as marked at the tops of the columns in the chart, were: 81, 86, 101, 62, 47, 43. The horizontal spaces in the columns represent blocks of tens in the number of cases treated. Here, at a glance, one sees the decided effect of the working of the plan when applied in the spring of 1883.

The argument has often been advanced that any attempt to reform abuse of medical charity would lead to scarcity of clinical material for instruction. The writer's figures refute this in a marked manner; for while this scheme was in action, the number of cases coming to the Dispensary increased from 381 in the six-months interval in 1882, to 413 in the like interval in 1883. The number of cases increased in the whole district from 510 in a six-months interval in 1882 and 1883, to 618 in a like interval in 1885. Dr. S. Hall,[2] of New York, says that the Northern Dispensary of that city, at present, treats only two-thirds of the number that it did ten years ago, when indiscriminate charity was given, yet it does more real good in the cause of charity; and that the good done by a dispensary should be measured, not by the number of patients treated, but by their quality as regards their worthiness to receive medical charity.

After completing this paper — the most of which was written some months ago — a thoughtful paper of Dr. Hasket Derby[3] came under the notice of the writer. He seems to have hit upon much the same plan as above detailed, although no results are given as to the working of it, which would be much more difficult in such a field, namely, in an in-patient service made up of patients living over a wide territory. The plan is to combine the duties of an amateur detective with those of the physician, in suitable cases. Dr. Derby says: "passing over other plans, the solution of the whole matter seems to me so simple that I mention it with diffidence. It is but to accept the principle that the out-patient department is for the benefit of those whose lack of means would prevent their obtaining relief elsewhere, and to leave the application of this principle to the physician in attendance." He further points out that "police work" of this description, though distasteful, is not as onerous as would at first sight appear, as in regard to most of the cases, there is little or no doubt. He further continues:

[2] New York Medical Record, November 28, 1885, p. 616.
[3] Boston Medical and Surgical Journal, November 12, 1885.

"and when anything in the dress, manner, or statement of the individual causes hesitancy to be felt, a few questions, put with tact and kindness, will readily resolve the matter; or if any doubt should still be felt, the applicant for aid should certainly receive its benefit. It is not pretended that the medical examiner will be infallible, but we claim that fewer mistakes will be made by him than by any other to whom this task may be delegated."

In taking leave of the subject, I wish here to record my opinion, that by practice of the above-detailed plan, abuse of medical charity in the dispensary district of which the writer has charge has been almost completely stopped. Let the above-mentioned experience and figures bear me out. How far the scheme is applicable to similar practice in other sections is for others to judge.

A NOT WELL-RECOGNIZED SOURCE OF DOMESTIC POISONING, WITH CASES.[1]

BY CHARLES HARRINGTON, M.D., OF BOSTON.

The attention of the medical profession has frequently been called to the poisonous effects produced by stockings, gloves, and other articles of wearing apparel, in the dyeing of which, compounds of arsenic, antimony, and tin have been employed. But so far as I am aware — and I have made numerous inquiries, besides consulting considerable medical literature — little, if anything, has been said or written as to the possibility of poisonous effects from such articles dyed with the aid of compounds of chromium.

The use of chromium mordants has been, until quite recently, comparatively limited, owing to an ignorance of satisfactory methods of application. At the present time, however, they are very generally used, and one of them — the bichromate of potassium — is regarded as by far the most useful mordant for woollen goods. All of them yield excellent results both as to color and fastness, but the bichromate is the most valuable, and capable of the widest application. The employment of any other compound containing an equivalent amount of chromium is said to yield to the woollen fibre the mordanting body (the chromic oxide) not so completely, and to produce colors which are not equal in intensity. The only chromium salt which approaches the bichromate in effectiveness for woollen dyeing is chrome alum, but its use requires the addition of large amounts of bitartrate of potassium, and in any case, it is not equal to the same amount of the bichromate. Besides yielding the most excellent results, the bichromate possesses the additional qualification of being most easily applied.

The range of colors produced by the aid of the chrome mordants with the various dyestuffs is very wide, and includes many shades of brown, brownish-red, claret reds, olives, yellows, old golds, purples, blues, black, buffs, and grays.

It is a well-known fact, that the workmen employed in the manufacturing and handling of bichromate of potassium are almost without exception subject to the so-called "chrome disease," in which severe ulceration of the skin and mucous membranes, and perforation of the nasal septum are the most marked and common symptoms, produced by the irritating and corrosive action of the dust to which they are exposed; and it seems not unreasonable to suppose that under favorable circumstances, equally severe symptoms might be brought about by the wearing of apparel in whose fibre compounds of chromium have been precipitated. And further, it may be assumed that the accidental introduction of dust from the same cloth into the stomach might well be followed by the characteristic symptoms produced by the ingestion of chromates.

I have been informed by a scientific man engaged in the dyeing industry, that such hypotheses are unreasonable, because the chromium is precipitated in the fibre in an insoluble form, but the same objection may be applied with equal force to the cases of poisoning which have frequently been reported as due to the use of arsenic, antimony, and tin mordants, and to the ingestion of chromate of lead.

Although I have as yet been unable to find any reported cases traced to this cause, I can have no doubt that such cases are common, though their cause may not be recognized, for within a comparatively short time several have come under my own observation, in which the cause seems to be beyond dispute.

These cases I will briefly describe.

Case I. The patient, a stout, healthy-looking woman of perhaps forty-five years of age, by occupation a cap-maker, purchased between fifty and seventy-five yards of dark blue cloth for the manufacture of military caps, such as are worn by the boys of the public schools. The cloth was of much more lustrous appearance and considerably cheaper than that which she had ordinarily used. After thoroughly sponging the whole lot, she began cutting out the caps, which occupation required several days. Within a very short time she began to suffer from an intolerable itching of the hands, face, neck, and scalp. At the same time, she began to be troubled with intense thirst, which no amount of drinking could allay. There was much soreness of the eyes, nose, and mouth, burning in the throat, and feeling of discomfort in the stomach. Owing to the heat in the workroom, she dressed as loosely and lightly as possible, so that her body became more exposed to the dust from the cloth than it otherwise would have been. The itching became general, and so intense that she was obliged to remove her entire clothing every day and bathe her body with cream-of-tartar water, which gave only slight and temporary relief. The itching of the scalp caused such constant scratching that she was ashamed to ride in the horse-cars or be seen on the street except after dark, since she was obliged to carry her bonnet in one hand while she scratched with the other. In a very short time after the beginning of the symptoms, there was considerable ulceration of the neck, breast, thighs, and hands. The ears were much swollen, and became, as she expressed it, "running sores." On the hands, the soreness was most marked about the nails. On the completion of the cutting-out process, she began sewing the pieces together to make the caps, and the soreness of the fingers was much increased by the frequent pricking of the needle. There was now very intense pain in the fingers, which, one by one, were disabled and very much swollen. The ulcerations about the nails were much aggravated, and there was sloughing. In a short time she lost three nails from one hand and two from the other. The intense pain, itching, and thirst prevented sleep, and at last she was obliged to give up work. Up to this time she had had

[1] Read at the Annual Meeting of the Massachusetts Medical Society, June 8, 1886, and recommended for publication by the Society.

no idea as to the cause of the trouble, nor had she received medical attention. At last, however, being thoroughly alarmed, she consulted a physician, who concluded that she was suffering from the effects of poison, and advised her to have the cloth examined for arsenic. The cloth was submitted to me for examination and proved to contain no arsenic, but it did contain a large amount of *chromium*.

Work on the cloth was at once discontinued, and in a short time the main prominent symptoms diminished in intensity and disappeared. Her general health is not yet fully restored, although nearly two years have elapsed since the use of the cloth. The symptoms in this case were undoubtedly due to dust from the cloth, which not only was deposited on the skin, but inhaled through the nose and mouth. At the time when the itching of the scalp was at its height, the woman's two children, who lived at home and had nothing to do with the work, began to be troubled with itching and burning in the same place. On inquiry, it was learned that the mother and children used the same hair-brush, and thus the dust had been transferred from her head to theirs.

Some weeks ago, she had occasion to again handle the unmade caps. Each piece was dusted and packed away, the operation requiring considerable time. On the following day, her hands were very sore, the nails being particularly affected, and since that time one of the latter has come away.

CASE II. A clergyman of about sixty years of age, of active disposition and of good general health, purchased a pair of brown mixed woollen gloves, which he wore for three or four days, during which time he took several long walks. His hands have a tendency to perspire freely, though whether they did or not on these occasions he is unable to recall. He noticed a slight redness and irritation of both hands and wrists, but not suspecting the cause, he continued wearing the gloves. Three or four days later the irritation increased. It extended from the middle joints of the fingers to a line on the arms corresponding to the somewhat long wrists of the gloves, and it was this limitation which called his attention to the gloves as a possible cause of the trouble, and they were laid aside. To use his own description, "at first it was in the form of pimples, but afterward many of them ran together and became blotches."

The pain and irritation continued a month or more, during which time considerable ulceration occurred. At the end of another month, the ulcers, which were quite large and deep, had nearly healed. About this time he submitted the gloves to me for examination. They proved to contain no arsenic or antimony, but a large amount of *chromium*.

CASES III and IV.— Two boys, aged respectively five and a half and four years, children of a physician, complained, on the evening of March 28th of this year, of not feeling well, and referred the feeling to the stomach. After the administration of a small dose of aromatic syrup of rhubarb to each, they were put to bed.

At five on the following morning the elder awoke complaining of pain in the ear, of nausea, and pain in the stomach. He soon began to vomit a yellowish watery fluid, which, unfortunately, was thrown away. There was considerable prostration, quick pulse, profuse cold perspiration. He vomited in all about a half dozen times. The gastric pain was very severe all day, and was accompanied by headache. In the afternoon he seemed very heavy and stupid; the headache was now at its worst. The temperature and pulse were high; the cheeks flushed. He complained of pain in the lips, gums, tongue and throat. The lips were swollen; there was intense thirst, which water could not allay.

Meanwhile the younger boy, who had been dressed as usual, began to complain of nausea, and was undressed and put to bed. He soon had all the symptoms of the other, but in no such marked degree. The mouth and gums were very sore.

Up to the time of the first symptoms both boys had been in good health, had not eaten anything out of the ordinary, and had not been exposed to any unusual conditions. In searching for a cause of the trouble there was but one point called to mind wherein their habits and surroundings differed from those of a week and more before, and that was in their clothing. For four days previous to the first symptoms they had been wearing new suits of brown woollen cloth. Their mother, having had a previous experience with arsenic and antimony in stockings, suggested the possibility of poisoning from these substances, and the cloth was submitted to me for analysis. Before testing for the substances mentioned, I looked for compounds of chromium, which when taken internally, produce symptoms similar to those described. The result of the examination showed that *chromium* was present in great abundance.

But in spite of this fact and of the similarity in the symptoms, the diagnosis of chromium poisoning could be ranked only as a possibility. The symptoms in both children were general, whereas one would naturally expect some local action on the skin if due to dust from the cloth. Examination of both boys showed total absence of even slight reddening. It seemed hardly possible that the dust, which, by the way, was given off freely on shaking the cloth, could have produced such severe general and local symptoms. Careful inquiry as to the means by which the dust could have been introduced into their systems developed the fact that one child constantly sucked his fingers, and that the other was in the habit of biting his nails. The diagnosis seemed then more probable, but perhaps not susceptible of verification.

On consultation it was deemed advisable to administer a cathartic in order to remove any possible poison from the intestinal tract, and about 11 P.M., each child was given a dose of castor oil. White of egg beaten up in milk had been given to each some time before the administration of the oil.

The urine was very scanty and contained a slight trace of albumen.

During the early part of the night the elder boy got some sleep, but was constantly tossing and moaning. At four in the morning he had a severe attack of convulsions, with delirium. The younger had twitching of the muscles, but not so severely as the other, and there was no delirium.

The temperature of the elder was 102.6°; pulse 130, weak. The face was very red, and there was profuse perspiration. The temperature of the younger was 101°; pulse 120.

After some time the elder fell into a stupor, from which he could only with great difficulty be aroused. The mouth was swollen, painful and dry. Earache in both was very severe. Both had dejections following

the administration of the oil, and these were saved for examination.

The stupor, high temperature, pain in the mouth and intense thirst of the elder persisted all the next day. His temperature at night was 103.4°; pulse 140. He passed a rather better night, but continued to be dull and stupid in the morning. He complained still of pain in the mouth and tongue; temperature 101.4°. On the following day there was perceptible improvement, though still dull and heavy. There was a return of pain in the ear, and the membrane was punctured. There was occasional pain in the head and abdomen. The urine increased to a normal amount and was free from albumen. Meanwhile the symptoms of the younger had disappeared and he was up and dressed as usual.

From this point onward the elder improved slowly with occasional relapses. Nine days after the the appearance of the first symptoms, he had several bright bloody stools, which were preceded and followed for several days by stools containing much slime. Four weeks later, he had improved very slowly, and was thin, pale and generally out of condition. The dejection first following the administration of the castor oil was subjected to chemical analysis, which resulted in the detection of traces of chromium, thus establishing the diagnosis of poisoning. The bloody stools which occurred on the ninth day would seem to indicate sloughing due to the local action of the poison.

The history of the two last cases present a very remarkable similarity in symptoms to those of two children who were fatally poisoned by very small amounts of lead chromate, reported in Eulenberg's "Vierteljahrsschrift für gerichtliche Medicin," and quoted in all the recent works on toxicology.

Whether in these few cases the compounds formed by the mordant and the dye-stuffs are in themselves the active poison, or are decomposed by the secretions of the body with liberation of simpler chrome compounds, cannot yet be definitely answered.

Reports of Societies.

AMERICAN OPHTHALMOLOGICAL SOCIETY.[1]

CATARACT EXTRACTION WITHOUT IRIDECTOMY.

by Dr. H. Knapp, of New York.

Of the new operative measures which he had seen in Europe there were two above all others which he thought worthy of being tried, one was extraction without iridectomy and the other, advancement of Tenon's capsule. Of the fourteen cataract extractions which he had made since his return the last six had been without iridectomy. Three of these had made ideal recoveries, no reaction, clear, central, movable pupil, neither an anterior nor a posterior synechia. The other three had more or less posterior synechia, leaving the pupil ragged and somewhat obstructed, yet the adhesions were simple, not spreading a pseudomembrane over the area of the pupil. Vision was fair and could be rendered excellent by a simple needling if remaining insufficient.

He followed Panus in the performance of the operation, large section along the upper margin of the cornea, free laceration of the capsule, expulsion of the cataract and its remnants, reduction of the iris with a probe if it did not occur spontaneously. Before the operation the eye is fully cocainized, the lids and conjunctival sac washed and sterilized. The instruments and hands are treated in the same way. After the expulsion of the lens, a small quantity of an antiseptic is injected into the anterior chamber along the whole section and eserine instilled into the conjunctival sac. The speaker believed that the chief advantage of this operation lies in the possibility of keeping the wound perfectly free from foreign substances, including portions of the lens, capsule and iris. How often anterior and posterior synechiæ occurred, what the final visual results were, and how frequently after-operations would be required, were questions which could only be answered by extended statistics.

REPORT OF FIFTY CASES OF CATARACT EXTRACTION,

by Dr. David Webster, of New York.

In seventeen cases the operation was done under ether, in twenty-seven under cocaine, and in six no anæsthetic was employed. The results were successes, 41 cases or 81 per cent.; partial successes, 6 cases or 12 per cent.; failures 3, or 6 per cent.

Aseptic precautions were used in all the operations. The best vision obtained in any case was $\frac{20}{xx}$. Dr. Webster advocated the extraction of both lenses at the same sitting in judiciously selected cases.

Dr. Webster also related the history of a case in which he had relieved the pain in a glaucoma absolutum by lacerating the infra-trochlear nerve (Badal's operation).

DEATH OF A PATIENT ON THE FIFTH DAY AFTER THE EXTRACTION OF A HARD CATARACT,

by Dr. Henry D. Noyes, of New York.

On Sunday morning, the operation, which was perfectly satisfactory, was performed, and the patient suddenly died the following Friday morning. After the operation a bandage was applied and the patient put to bed. The dressing was not disturbed until the third day. Everything seemed to be doing well and the patient made no complaint. On Friday morning she suddenly complained of a feeling of prostration, and within half an hour she died. The only lesions found at the autopsy were dilatation of the heart and insufficiency of the valves of the left side. The death seems to have been due to heart failure. The contents of the orbit were removed *en masse*. A certain amount of force was used and as a consequence the corneal wound was partially ruptured. The eye-ball was hardened and ten sections have been made and they demonstrate the kind of union which we have at the end of the fifth day. Inspection of the eye before death showed that the union was smooth and apparently perfect. What is particularly interesting about these specimens is that the union appears to have taken place exclusively through the medium of the epithelial layer.

DISCUSSION.

Dr. David Webster, of New York. In regard to the use of cocaine, the more I have employed it, the more do I see the necessity of using as little as possible in cataract extraction. Some of my cases that have done badly I think were due to the use of too much cocaine. In my later operations I have done about as Dr. Strawbridge has recommended.

[1] Continued from page 114.

DR. B. JOY JEFFRIES, of Boston. In cataract extractions I have found it of decided advantage to instill cocaine into both eyes. One drop a minute or two before the operation is sufficient. It renders the eye quiet and the patient can keep it open.

DR. C. R. AGNEW, of New York. Probably the best plan to follow in the use of cocaine is to instill a drop of a four per cent. solution and hold the lids open to allow it to become diffused. Then wait three or four minutes. The eye may then be touched with an instrument to ascertain whether or not the sensitiveness has been sufficiently obtunded. One or two drops are usually sufficient and employed in this way the possibilities of evil effects are reduced to a minimum.

It has never been our custom in New York to incarcerate patients in the dark after a capital operation on the eyes.

DR. W. F. MITTENDORF, of New York. I have had two cases of serious complication after cataract which I attributed to the use of cocaine. In one the eye was lost and in the other it came near being lost. The cocaine solutions were fresh, but they were strong and used freely. I have thought that one reason bad results are obtained, is because the eye is left exposed to the air for several minutes after the introduction of cocaine solution. Recent observations show that the injurious action of cocaine is especially upon the epithelial layer and in shutting off the supply of lymph fluid. The epithelium suffers very rapidly from lack of moisture, especially if the eye is kept open. It has been recommended to close the eye immediately after the introduction of cocaine. I use a weaker solution than a two per cent., making it fresh every day by the addition of one or two grains of cocaine to half an ounce of water. Since I have used the weak solution and have closed the eye after its instillation, I have had no serious accident.

DR. WILLIAM THOMPSON, of Philadelphia. In regard to the efficiency of a weak solution of cocaine, I may say that the first time I used cocaine, I directed the apothecary to make a two per cent. solution. Instead he made a solution of two grains to the ounce. I did three operations with it with perfect success and did not find out until afterwards that a mistake had been made. Since then I have not considered it necessary to use strong solution.

DR. EMIL GREENING, of New York. Last summer I went to Dr. Wecker's clinic to see him perform cataract extraction without iridectomy. I learned that he employed this method only in the winter time. The reason for this is, that during the hot weather of summer the patients were very restless and that as a result prolapse of the iris frequently occurred. I decided to try the operation when I returned and on May, 1886, I performed my first operation. Half an hour before the operation I instilled a few drops of a solution of eserine (half a grain to the ounce). A few minutes before the operation, the eye was cocanized with a four per cent. solution. There was no difficulty in removing the lens. After the operation eserine was again instilled and the eye bandaged. Forty-eight hours later, I removed the bandage. The patient made pressure on the eye-ball, the anterior chamber was emptied and the iris prolapsed. I was compelled to remove the iris. There were no further accidents. A few days later, I operated on a second case with perfect success. In regard to the action of cocaine, I may give an extreme example. It was a case of an acute exacerbation in chronic glaucoma. The eye was very painful and very hard. I directed that a six per cent. solution of cocaine should be instilled. A few minutes later on opening the lids and introducing the speculum a bladder arose between its blades. Examination showed that this was the epithelium of the cornea which had become raised. The operation of the sclerotomy which was about being performed was postponed, but it eventually became necessary to remove the eye-ball.

DR. H. D. NOYES, of New York. I have performed extraction without iridectomy in six cases. I have used cocaine, and the cleansing of the anterior chamber and the removal of lens matter, has been accomplished partly by manipulation and partly by irrigation. For washing out the conjunctival sac and removing matter from the anterior chamber I use a rubber bulb holding two or three ounces and terminating in a short nozzle. It is not necessary to introduce a nozzle between the lips of the wound. The iris may be satisfactorily replaced by a stream of water. I have also used eserine not as a preliminary but as a dressing, using an ointment containing two grains of eserine to the drachm of vaseline. A small portion of this is placed in the conjunctival sac and spread on a piece of linen covering the eye. In three of the six cases there was perfect union with a central circular pupil and accurate vision. In one case intra-occular hæmorrhage came on twelve hours after operation, but this might happen under any method. In two cases prolapse of the iris was found on the seventh day when the eye was carefully examined for the first time. The prolapsed iris was excised and in one case the result was entirely satisfactory. In the second case no satisfactory vision was obtained.

The impression on my mind from this small series of cases is, that while the operation deserves attention the cases must be carefully selected. If the patient had but the one eye, I think that I should operate on it with a preceding iridectomy and not without. My belief is that a satisfactory result can be more certainly secured with iridectomy. As to the visual result, while theoretically it should be better it is not always so.

DR. SAMUEL THEOBALD, of Baltimore. In a case in which cocaine was used where there was stricture of the nasal ducts, I invariably observed that after the instillation of cocaine, the cornea which had been clean and bright became dull, presenting the appearance as though it had been roughly handled. I have noticed a similar result in another case.

DR. B. E. FRYER, of Kansas City. In about ten cases I have used cocaine in this way: inserting one drop every half hour until four or five drops have been used. In this way the iris becomes completely anæsthetized, and where we wish to perform iridectomy this is important.

DR. B. ALEXANDER RANDALL, of Philadelphia. There is one point not distinctly referred to in the discussion and that is whether or not inflammation of the iris is more frequent after this operation than where iridectomy is done. In the thirty or more cases which I saw at the clinic of Panas, two years ago, there was not a single case of iritis. There were, however, several cases of prolapse. Panas claimed that there was less inflammation than after the ordinary operation. It is proper to say with reference to iridectomy that with a small iridectomy the pupil may

be as movable and as central as in the operation described.

SOME MEDICO-LEGAL CASES,

by B. Joy Jeffries, of Boston.

The author first read the law of Massachusetts in regard to the examination of railroad employés and others for color-blindness, and stated that it was practically a dead-letter and could not be enforced. In order to make it efficient some standard must be adopted. Many instances in which the law had been evaded were given. Many cases were cited, particularly of railroad engineers and steamboat pilots, where lives of passengers had been endangered by this defect.

Dr. Charles A. Oliver, of Philadelphia, exhibited and read a description of a new series of loose wools for the scientific detection of sub-normal color perception (color-blindness).

They comprise ninety-seven bundles of Berlin worsteds, composed of five large principal test-skeins, twenty small pure match skeins, and seventy-two small confusion skeins. To each small skein there is attached a metallic handle bearing the exact equivalence of the color's composition, tint and shade stamped upon it in a way that can be only understood by the surgeon. The colors are all of equal relative intensity. The wools are all of one manufacture and have been dyed with vegetable materials.

The following advantages are claimed for the series: That there are five tests, that the wools are loose and all of the colors of the same relative intensity, that each skein has its value expressed so that they can be employed by any intelligent layman, that accurate noting of color changes can be made for future comparison, and proper verbal and written expression can be given, that by reason of the wool all being made of the same grade of manufacture and all the colorings obtained from vegetable dyes, no results can be gotten from the supplemental use of touch, and finally, that a black surface is employed and no definite order of testing need be pursued.

Dr. William B. Dennett, of New York, exhibited a set of Holmgren's worsteds, which had been made into spheres, to each of which a number was attached. It was thought that considerable elegance and some advantage would result from using Holmgren's or Thompson's test in this manner.

Adjourned until evening.

FIRST DAY. — EVENING SESSION.

Dr. Samuel B. St. John presented a communication from Dr. Bolton, of Trinity College, to the effect that he had discovered that his grandfather, Dr. North, had founded in New London, Conn., in the Spring of 1817, the first Eye Infirmary established in the United States.

The first paper read was on the

EFFECT OF THE ELECTRIC LIGHT UPON THE EYE,

by Dr. J. A. Andrews, of New York.

The injurious effects of various forms of light upon the eye were first considered and numerous instances cited showing the harmful effect of exposure of the eyes to bright sunlight, bright lamplight, and to the reflection of the sunlight from snow. Cases were given in which a short exposure to the arc-light was followed by swelling of the lids and conjunctivæ. These symptoms yielded to sedative applications. The effects of lightning have been classed with those due to bright light, but they are different. The effects of lightning are probably due to the physico-chemical action of the electric current causing coagulation of the albumen in the crystaline lens. The opacity of the lens occurring among glass-blowers seems to be chiefly due to the intense heat to which the eyes are exposed. The speaker had found lenticular cataract in four per cent. of glass-blowers, under forty years of age, and in twenty per cent. of those over forty years of age whom he had examined.

In considering the relative effect of different forms of illumination, that obtained from gas, from kerosene, and from the electric light were studied. The electric light gives the maximum of light with the minimum of heat. So far, the only cases of injury to the eye from the electric light, have resulted from exposure in close proximity to the intense light of the arc-light. In most of these cases the existence of previous eye trouble was not excluded. The effect in these cases can be best explained as occurring through the sympathetic nervous system rather than as a result of mechanical or chemical influences. It is not established that exposure to bright light can produce a diffused iritis. No case of injury to the eye from the incandescent light has been reported and out of eleven hundred workers with the electric incandescent light examined by the author, there was not one complaint. Those suffering with errors of refraction, claimed that the sight was improved. The light used was from twelve to sixteen candle and provided with a shade to protect the eyes. The incandescent light possesses advantages which are wanting in other forms of artificial light, the principal of which are its steadiness and the fact that its use does not contaminate the atmosphere.

DISCUSSION.

Dr. C. R. Agnew, of New York. We have introduced the incandescent electric light into Columbia College reading-room. All who have made use of it have expressed great satisfaction with it.

Dr. W. F. Mittendorf, of New York. Dr. Andrew's paper confirms the results of my observations. The popular feeling has been against the electric light as injurious, but my experience proves the contrary. The light is so perfect that the work need not be approached so close to the eyes, and the efforts of accommodation are less. On account of its steadiness less work is thrown upon the pupil than with the flickering light of the gas-burner.

The next paper was on

A METHOD OF OVERCOMING DIPLOPIA WHEN PRISMS ARE NOT FULLY EFFECTIVE,

by William S. Little, M.D., of Philadelphia.

Double vision, especially in the lower field, is a source of danger in walking. This is the case, even where prisms are worn, as the patient by not holding the head forwards may look under the spectacle and thus see double. A case of an elderly person with modified paresis of the superior oblique was described. This had led to two severe falls. A prism of six degrees, properly placed, united the double images below the horizontal plane. Above this plane the objects are single. Myopia also existed in each eye and required the combination of a sphero-cylinder with a

prism for the right eye to correct the myopia and diplopia. In order to prevent looking under the glass and seeing double in the lower field, the speaker had resorted to the following procedure. The spherocylinder correcting the myopia of the right eye has been ground opaque for one-sixteenth of an inch above the horizontal plane, so as to obliterate sight in the lower field of vision in this eye. Then there had been attached to the lower portion of the frame, the wire net-work used in protecting glasses. This is carefully adjusted to fit close to the face, the perforations in the gauze having been stopped by painting. Vision is thus cut off below and under the spectacle. In this way, vision for the the affected eye is only through the upper part of the myopic correction and the necessity for a prism is done away with. The other eye has its myopic correction and is the one in which vision in all parts of the field is clear. The right eye is only used in the upper part of the field where no diplopia exists. This is better than entirely closing the affected eye by a ground glass and is found more effective than with the prism, as danger of falling by seeing double is prevented. The same method may be applied to a diplopia in any position in the visual field.

The spectacles as made by Borsch and Rommel were exhibited.

TWO EPIDEMICS OF MOLLUSCUM CONTAGIOSUM,

by DR. W. F. MITTENDORF, of New York.

The contagiousness of this affection has been a matter of much dispute. The two epidemics which had come under his notice had occurred in asylums for children. In the spring of 1885, a little girl having one or two small "warts" on the eyelid was admitted to one of these institutions. In a few weeks other children exhibited similar growths on the eyelids, in some cases spreading to the lips and to the nose. Within three months after the admission of the first case, twenty-seven children were more or less disfigured by this affection.

In the second institution as many as forty children were affected at one time, Some of these children were sent to board with a farmer. One of twenty thus sent out, had molluscum. In a short time the affection spread to over half of the children. It also attacked the child of the farmer and his wife. In a number of cases the tumors involved other portions of the face, but they were most marked on the lids.

As soon as attention was called to the condition, energetic treatment did away with it. Excision with scissors and touching the base with nitrate of silver proved most satisfactory. Simple pressing out of the matter is more painful than excision. Unless the latter is employed the disease is apt to return.

(To be continued.)

— A correspondent of the *British Medical Journal*, who has had considerable experience with hydrophobia, writes that his cases lasted, from seizure to death, three to five days. They were constantly under observation. He found that fluid, when darkened, could be taken in forced gulps, but not from a glass vessel; it could be taken from a cup where the contents were unnoticed until raised. Blindfolding only caused general resistance. Porter was found to give considerable temporary relief.

ANNUAL MEETING OF THE AMERICAN NEUROLOGICAL ASSOCIATION.

JULY 21st, 22d, 23d, LONG BRANCH, N. J.

FIRST DAY.— MORNING SESSION.

DR. BURT G. WILDER, of Ithaca, N. Y., in the chair, on retiring, addressed the meeting as follows:

In view of the fact that he had delivered a somewhat extended address upon a general subject last year, he would confine his remarks to the brief discussion of what he believed to be a new fact, namely, the accurate collocation of a suture and fissure in the human fœtus. In three alcoholic fœtuses in the Cornell University, estimated to be from three to seven months advanced, the lambdoidal suture directly overlies a short but deep fissure which has seldom been noticed, and has been hitherto uninterrupted and may be called the lambdoidal fissure.

A photograph and drawing of one case were submitted: the fissure was very distinct and deep, but had no ental corelative in the cases examined. The doctor remarked that Bischoff and Huxley had regarded the fissure itself as temporary in man, though persistent in apes. Prof. Wilder believed the fissure to persist in man also: but to loose its relation with the suture in the last two months of fœtal life. He mentioned the probability that the coronal suture is similarly related with a pre-central fissure, and closed his remarks with an enumeration of several questions that arise in connection with the subject and with the suggestion as to making use of fœtal brains by careful exposure, preservation, photographing, etc.

Professor Wilder then introduced to the Association, Dr. Charles K. Mills, of Philadelphia, the President of 1886.

DR. MILLS, on taking the chair, made a few introductory remarks on the work of the society and the proposed Congress of American Physicians and Surgeons.

He then presented specimens and described with his usual lucid remarks, the brains of a monomaniac, a murderer, an idiot, a negro, and a Chinaman, drawing attention to the importance of the study of the cerebral convolutions.

The doctor congratulated the Association upon the large amount of published work which had been done by its members since the last annual meeting, instancing the fifth volume of Pepper's American System of Practical Medicine, out of the twenty-four contributions of which, more than one-half were from members of the American Neurological Association. He urged the importance of individual effort towards increasing the membership of the Association, so that it would be in fact as well as in name — the great national representative of those members of the medical profession who are interested in neurology and pschycology, and the branches of science which are specially correlated to those subjects.

He discussed at some length and with approval, the project for the formation of a Congress of American Physicians and Surgeons, he also stated that difficulties might arise in connection with the initiation and inauguration of the Congress. He spoke of danger apprehended by some, that the Congress like another national medical body might drift insensibly into the arena of medical politics, but believed if wisdom prevailed during its development, that such might be

avoided. He thought it would be better for the meetings of the Congress to be biennial, thus allowing the Association as special organization, to have entirely separate and independent meetings on alternate years. He also believed it desirable to have the meetings of the Congress held at a fixed location and thought Washington the most desirable, but that should be decided upon by a committee of conference. He would suggest also that no one should ever be re-elected to the position of President of the Congress; and also that the sessions of the Congress should be held in the mornings in order to allow the various sections to attend to their own special work as in the sections of the American and the British Medical Associations. The doctor also believed it right that the authors of scientific contributions should be allowed the privilege of publishing them in any of the medical periodicals.

The doctor then produced the brain of Burke, a delusional monomaniac, that of Taylor, an alleged delusional lunatic, executed in Philadelphia, also of a feeble-minded youth from the Pennsylvania Training Institution for Feeble-Minded Children, as well as the brain of a negro and a Chinaman. The brain of the Chinaman was first exhibited at the Philadelphia Neurological Society, by Dr. A. J. Parker. Dr. Mills stated that it is the first Chinese brain that has ever been described as far as he knew. In discussing the appearances presented by those specimens he gave what he regarded the peculiarity of human brains of low type and also the differences between simian and human brains. He demonstrated that in the white adult brains presented and also in others of which descriptive notes were read, that there were easily recognized differences between these, and those of individuals of better grade. In all the assimitry was distinctly typical, both of lobes and gyral fissural arrangement, which he believed to exist in a marked degree between the two hemispheres. In general terms the white brains were found to approach more nearly in type the brains of the negro, ape, and to the fœtal brain than is ever the case in an ordinary adult white brain even, in individuals of moderate intelligence and intellectual power. He discussed the question whether these specimens, some of them from men who had committed crimes of violence, who had taken the lives of their fellows, sustained the conclusions of Benedict and others, that the brains of criminals are absolutely distinctive; that we have a criminal type of brain which can even be separated from the type which can be found in other forms of insanity. Such a generalization he regarded as too narrow.

In the brains presented, there were certain points of affinity noted, and points of difference from known conditions of higher human types; these so great as to allow him to put them into a class together as representatives of brains of low types. He regarded the attempt however, to construct a theory as to the anatomical basis of crime, as in some respects unphilosophical; criminals and transgressors of the law being of the most diverse character. The doctor criticized some of Benedict's conclusions although he paid a tribute to his observations and regarded them as stimulating research to a wonderful degree. He thought it strange so little research had been made in the Chinaman's brain heretofore, and that although we have a large negro population but little had been done towards the mapping out of the negro brain. He remarked that no Indian brain had ever been described in detail, and thought some of our army surgeons on frontier posts, who had such great facilities for such investigations should undertake this interesting work. Dr. Mills also stated that he looked in vain for a description of the condition presented by the cerebral surface of an intellectual woman.

DISCUSSIONS UPON SPECIMENS PRESENTED BY THE PRESIDENT.

Dr. Wilder remarked that the subject was worthy the importance which the President had assigned to it, and he was afraid there was a large number of physicians and surgeons who were not as familiar with the brain as they ought to be, and he considered it the highest compliment the President could pay to the Association in speaking in the straightforward manner he had assumed in his paper in relation to the anatomy of the brain. He would like to have examined the brain of the Chinaman more thoroughly, in order to confirm some of Dr. Mill's statements, remarking that, in the negro brain, he had called attention to the exposure of the insular in it; but Dr. Wilder remarked that he had one where it was still more exposed, and in the specimen he spoke of, the brain was hardened in the skull, so that there was no chance of undue pressure; he noticed that the Chinaman's insular was abnormally covered, but he thought it would not do to credit the Chinaman with it, as he noticed the brain had been flattened upon one side, and the first temporal convolution had been pushed over the insular. He also agreed with the President in his remarks upon Benedict's generalization. He thought, however, they merited careful scrutiny. With regard to the confluence of the Rolandic fissure and the Sylvian, he remarked he should hesitate to say anything, but in some twenty or thirty brains that he had, he had never seen the confluence with the central and the Sylvian. The Doctor thought that it would be a difficult matter to find an average brain, and he suspected it was the same with a large number of others; he thought the brains that were studied were more or less peculiar, giving, as an instance: some year or more ago he secured some six human brains for his students to dissect, but upon examination, each of them had some peculiarities, and he concluded they were too valuable for ordinary dissecting. He then asked the President if, supposing he had not known this to be a Chinese brain before him, whether he would have known it, or rather, whether he would have felt disposed to note its peculiarities; if there was anything that would lead him to think it belonged to a different race from our own.

Dr. L. C. Gray, of Brooklyn, remarked that he did not think there was any disagreement among our neurologists as to the one-sided manner in which Benedict's researches were conducted. He thought it was unfair of Dr. Wilder to criticise upon any one point in a paper which contained so many peculiarities until after a careful examination of the specimen. He thought that until some one has determined the limitation of the various convolutions in the human brain, it would be difficult to set the line. There were two points, he said, which had attracted his special attention; the Doctor stated that he had two negroes' brains, and there was some uncovering of the fissure of Sylvius; but he had never seen the fusion of the fissure of Rolando with the fissure of Sylvius.

Dr. Derkum remarked that some months ago he

had exhibited a brain from an epileptic female; the island of Riel was covered on both sides, but on one side the fissure of Rolando was confluent. He also remarked that Dr. Parker had described several fissures which had occurred in a negro brain on the mesial surface, which were afterward ascribed to mechanical causes.

MR. JOSEPH JASTROW, of Johns Hopkins University, by invitation of the President, stated that he had taken twelve or fifteen brains before him for class demonstration, and, after taking plaster impressions, had photographed them, and those where the convolutions came out more fully might be those of the normal brain. He thought with a better knowledge of the brain these smaller changes would teach us to understand the subject.

DR. BIRDSALL thought Benedict's theories were rather strained, but may have stimulated further research. He also opposed the view that one particular type of brain must form that of a criminal. He thought the study of the cranium in different races would be of advantage, but that the study was still in its infancy as to relation between these peculiarities and their functions.

DR. SACHS, of New York, remarked he was naturally interested in the general anatomical bearings of the fissures; he thought we ought to distinguish between the primary and secondary developments of the fissures. He remarked that it would have been important to know the conformation of the skull from which the brain of the Chinaman was removed; this, he thought, might prove an important factor.

DR. WILDER remarked he thought the discussion had been made in regard to the fissures which are considered as primary; he did not think much would be gained by speaking of the secondary fissure.

The PRESIDENT, in reply, said he agreed with Dr. Wilder that it would be better to harden brains in the skull. But in reference to the specimens he had shown, some of them were obtained under great difficulties, and he was glad enough to get the brains as they were. The fissure of Rolando, in one of the cases, was crossed by a convolution, instead of being confluent. It is true, as Dr. Wilder has said, many brains are peculiar, but perhaps it might be due to the reason that most brains we secure are from those of low organization.

In regard to the Chinaman's brain, he would not have known it belonged to a different race, but there was a peculiarity of appearance, but he could not understand what it was. Dr. Parker himself noticed the unusual shortness of the orbital surface. In regard to Benedict, he did not think we should be too severe in our criticisms, but he (Benedict) had a bad manner of generalizing, as he himself thought that criminals did present brains of a peculiar development and conformation; but he believed Benedict's statements to be that with different grades of criminals different types of brain were found; this, the President considered, was unscientific. In regard to Mr. Jastrow's remarks, he thought such experiments were very interesting in regard to studying the higher and lower types, but was not so certain of attaining a standard of the normal brain. The Doctor considered that Dr. Wilder had answered Dr. Sachs's remarks, and that he himself based his remarks upon the primary fissures principally.

(*To be continued.*)

Recent Literature.

Traité Élémentaire d'Anatomie Médicale du Système Nerveux. Par Ch. Féré. Paris: A. Delahaye et Lecrosnier. 1886.

Dr. Féré states in the preface that this is intended for a work on the applied anatomy of the nervous system, somewhat in imitation of Tillaux's anatomy with surgical applications. He has wisely touched but slightly on minute anatomy or at least on points of structure that demand high powers of the microscope for their elucidation. The author is to be congratulated on the clearness of his descriptions, and on the discretion with which has avoided much discussion of disputed points. He describes first the membranes and, to our surprise, adopts the view that the arachnoid is a serous membrane. He holds with Cruveilhier that the foramen of Magendie has no real existence, being simply a rent in the membrane. After the description of the brain, the arteries are considered at some length. The relations of the brain to the head receive due attention, and the author goes at length into the important question, in these days of cerebral surgery, of finding the bregma, or junction of the coronal and sagittal sutures, in the living. It is needless to say that the interesting subject of localizations is a prominent one. Pathological observations are frequently alluded to. We are struck repeatedly by the caution of the author and think that there is little in the book that cannot be received as demonstrated, at least till new discoveries revolutionize, as they well may, our ideas of the physiology of the brain.

After the central nervous system comes the peripheral and that of the sympathetic. In this, the descriptive anatomy is so much out of proportion to the applications that we are inclined to wonder why it was written at all, or why it was not, at least, much condensed. One of the most valuable features of this part consists of diagrams showing the electro-motor points on the surface. There are more than two hundred illustrations in the text, which are for the most part, borrowed. They are well-chosen though often poorly executed. T. D.

Aids to Obstetrics. (*Students' Aids Series*). By SAMUEL NALL, B.A., M.B. 16mo. pp. 142. Paper and cloth. New York and London: G. P. Putnam's Sons. 1885.

This, like the other numbers of the Students' Aids Series, will doubtless be of assistance in preparing for examinations. It is based on the works of Playfair, Leishman, and Lusk, and is in the main a safe guide. There are, however, several matters of opinion to which we should take exception, for example, the explanation given of the internal rotation of the head.

The great objection to these aids is, that the average student, if he thinks he can "pass" by their use, will neglect the larger works: we do not, therefore, believe in these short cuts to knowledge, and think they should be labelled, like certain country roads, "Dangerous Passing," letting the wayfarer take his own risks. And although these by-ways may generally lead safely to the journey's end so far as obtaining a diploma, we advise students to choose the broader, safer, albeit longer, highways to knowledge.

Medical and Surgical Journal.

THURSDAY, AUGUST 12, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & Co., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

MEDICINE IN THE UNITED STATES AND CO-OPERATIVE INVESTIGATION.

THE Address in Medicine before the British Medical Association at its annual meeting, held this year in Brighton, was delivered yesterday, by Dr. John S. Billings, of the United States Army, and is given to the readers of the JOURNAL to-day. It will be remembered that the late Dr. Austin Flint, of New York, was originally invited to deliver this address, and after his death what he had prepared was published by his son, the manuscript having been found among Dr. Flint's papers — an example of prompt preparation to meet engagements which many younger men would do well to imitate.

Dr. Flint had selected "Medicine of the Future" as the subject for his address, an editorial notice of which may be found in the JOURNAL for June 17th. Dr. Billing's address is on "Medicine in the United States and its Relations to Coöperative Investigation," and is well worth the space which its length demands from our columns.

The first part of the address, dealing with the present condition and future prospects of medicine in the United States, will naturally have less novelty and less interest for those who think they already know enough about the subject; but even these will find the summing up of the relations of the General Government and the individual States to medicine and to its practitioners a concise and felicitous one for reference. Pretty much the whole of the law and the prophets in regard to legislative regulation of medical practice is really condensed in the following sentences:

"To me it seems that the most important of the first steps to be taken in this direction is one which has already been taken in Great Britain — namely, the requirement that every death in the community shall be registered, and that in such registration satisfactory evidence shall be given as to the cause of death, sufficient at least to prove that such cause is what is known as a natural cause, that is, that it is not due to crime. When it is admitted that one of the duties of government is to provide for such registration, both in the interests of life and to secure the rights of property, it follows, necessarily, that those persons whose certificates as to the cause of death are to be accepted as satisfactory evidence that there has been no foul play, must present evidence that they are properly qualified to make such certificates. The principle is precisely the same as that which induces a government to provide for the examination of the medical men whom it employs in its army and navy.

"So far as the art of medicine is concerned, the demand has much, though by no means all, to do with regulating the quantity and quality of the supply; and there are few localities in the United States where the qualifications of the medical man is not fully up to the standard which the community is able to appreciate and is willing to pay for. In the natural order of things suffering and death are the remedies for ignorance, weakness, and vice, and the means of preventing the transmission of these characteristics to offspring. These remedies, though effectual are drastic, and we do our best to avoid them, but perhaps it is well that the penalties cannot be done away with altogether.

"The laws regulating the practice of medicine in the United States are all State laws. If we were to judge only from what may be found in the statute books, assuming that all the laws contained therein are duly enforced, we should find that nearly two-thirds of the States have laws ostensibly regulating the practice of medicine within their borders. As a matter of fact, however, in over half the States which have laws on this subject no attempt is made to enforce them, and in almost all of them the possession of a diploma, no matter from what source derived, is all that is required."

Dr. Billings, however, recognizes the gradual tendency here, as elsewhere, which the remarkable development of sanitary science, of preventive medicine, of State medicine, has to bring the great body of practitioners into closer relationship with the State — a tendency which, sooner or later, directly or indirectly, will force the State to exercise some control over the practice of medicine.

This leads up naturally to the second part of the address, the relations of medicine in this widely-extended country to coöperative investigation; for preventive medicine is at once a result and an incentive of coöperative investigation, and Boards of Health are, in the discharge of their most important functions, really bureaus of coöperative investigation. Dr. Billings deals with coöperative investigation in a broad and liberal sense, and is evidently not one of those who is unable to see any promise of good to come in the future, because present efforts at coöperation do not realize expectations at the mercy of a narrower field of vision. The coöperation of individuals, urged on by various motives, has given us, through various vicissitudes of progress, medicine as we have it at the present day, but the laboratories for experimental research of the present and the future, the Boards of Health, the Government bureaus, the great medical and scientific organizations, may reasonably be expected to hasten and extend the results of coöperative investigation in a way and to a degree that the blind impulse of isolated individualism would never have indicated. By references to his report on mortality and vital statistics of the United States, as returned at the tenth census, which exhibit some of the peculiarities in the distribution of deaths from certain causes — such as cancer, scarlet fever, diphtheria, pneumonia, consumption — Dr. Billings suggests the contributions to the common fund of medical knowledge which may be demanded from, and furnished by the United States in the future.

Through the Government bureaus at Washington and the State Boards of Health, "Medical Topog-

raphy" is already on the road towards a gratifying state of advancement in this country. And nowhere, as this address justly points out, are such combinations of conditions to be found for studying race problems of disease, which are simply problems of heredity taken in mass; nowhere are natural experiments upon such a grand scale to be observed as regards the effects of various peculiarities of climate, soil, altitude, food, and occupation in connection with variations in parentage under conditions of exposure to the same causes of disease.

We, Americans, need not hesitate to acknowledge ourselves as the heirs of the ages, to confess that we have received freely, for with the recognition of our debt comes the assurance that we can repay it handsomely. Dr. Billings rightly interprets the invitation to an American to give the Address in Medicine before the British Medical Association as an indication that we are thought not only willing, but able to pay some part of our debt to the common fund of knowledge.

LEPROSY IN THE HAWAIIAN ISLANDS.

DR. EDWARD ARNING, of Honolulu, contributes to the Board of Health of Hawaii a valuable report upon leprosy, a subject which in recent years has assumed great importance as affecting that island empire.

The report embraces five topics:

1. Clinical.
2. Pathologic and anatomical.
3. Special bacterial research.
4. Therapeutic.
5. Hygienic.

The clinical work embraces an inquiry into the historical features of the disease, and its symptomatology as found in the Islands. An interesting point of clinical importance is the existence of many cases of *abortive leprosy*, of which Dr. Arning has made careful observation and expresses the hope that these symptoms of arrested disease may be hailed as a proof of a decrease in the virulence of the disease in general.

Under the topic of pathologic-anatomical work, Dr. Arning had conducted seventeen post-mortems of lepers, the result of which would tend to modify opinions as to the disease being confined mainly to external parts. He found grave changes in the larger viscera, especially in the lungs, liver, spleen, and bowels, due to genuine leprous infiltration.

The question of etiology appears to have been carefully studied, embracing a search for the *bacillus lepræ* in the air, water and food, and the attempt to cultivate it in artificial soils of great variety and at different temperatures.

Various living animals were also inoculated, but without results after several months' trial. These negative results have induced Dr. Arning to state the following conclusions:

(1) The bacillus lepræ is a parasite limited to the human race.

(2) It must be transmitted either directly from individual to individual, or

(3) Run through an intermediate stage, which may be present in soil, water or food, into which it only passes from the diseased tissue of a leper.

(4) Accepting either theory, the direct or indirect transmission, we must look upon every individual leper, whether in the incipient or advanced stage, as a dangerous focus of the malady.

(5) The leprous germ requires a certain disposition of the human soil for its propagation. Such a disposition may exist concurrently with apparent good health.

Dr. Arning's experiments upon a condemned convict (whose sentence was commuted for the purpose of submitting him to experiment) are detailed so far as observations have been made. Bacilli were inserted in the arm, September 30th, and were still present in large numbers in the following March. After that time they diminished in number, but were still found in November, fourteen months after insertion.

Of the therapeutics of leprosy, which are classified by the writer as *specific* and *symptomatic*, he acknowledges the uselessness of the former class, so far as experience has thus far tested them. For the symptomatic treatment, considerable benefit, so far as the investigation of local manifestations is concerned, is derived from the use of sulphur, pyrogallic acid, corrosive sublimate and electricity.

Ulcerations of the mouth, throat and nose require the use of antiseptics, astringents, and medicated sprays, all of which alleviate the distressing symptoms for a time.

Hygienic measures. Under this important topic the writer briefly treats of the question of segregation and of the relations of leprosy to vaccination, including the medical examination of school-children. He strongly urges the use of bovine virus as a rule, with careful instructions for its employment in all cases. In support of this advice Dr. Arning vaccinated several lepers, and found the bacillus lepræ in the lymph and also in the crust.

The effect of immigration is also considered, especially from China, the Azores, and Japan, of which the writer says: "It is deplorable, though perhaps inevitable, that these islands, with their terrible abundance of leprosy, should be repopulated by the very nationalities who seem to have not yet overcome the disposition to the disease as much as other races."

Another important question is the *disposal of the dead* bodies of lepers. Leprous tissue was set aside under conditions of temperature and moisture, conducive to slow and thorough putrefaction. An examination of the remains of this tissue made eight months afterward, showed it to consist nearly entirely of "swarms of the bacillus lepræ," closely packed. This experiment prompted an examination of a portion of a body which had been buried three months at the leper settlement at Molokai, and in this instance leprous germs were found present in great numbers. As

a bar to the possible spread of the disease from this cause, cremation and the use of quick-lime are suggested.

In this connection the subject assumes considerable importance as affecting the welfare of our own population; with constant immigration to our western shores of people from the leprous districts of China, Japan and the Sandwich Islands, and to our Eastern ports from Norway, and with existing foci of the disease at San Francisco among the Chinese, in Minnesota among the Norwegians, at the little settlement at Tracadie in New Brunswick, and at a few southern ports, there is reason for the adoption of stringent measures for the prevention of its further introduction and spread.

The progress of the disease in the individual, from the beginning of its incubative stage is slow, but its progress among races or nations is often comparatively rapid. The first recognized case in Hawaii was not noticed till 1853, but in the third of a century which has elapsed, it now threatens the existence of that island people.

With the possibility of a similar spread at any point in the United States, a country having the greatest possible variety of climate, soils, food and other conditions, and also a similar variety of races in its population, it is incumbent upon the government to adopt measures which shall prevent the further introduction of the disease, and secure its limitation to localities where it now exists.

A timely paper by Dr. J. C. White,[1] entitled "The Question of Contagion in Leprosy," urged such a course, including the enactment of strict laws for its prevention, the adoption of quarantine regulations and inspection of all suspected persons from ports where leprosy exists.

MEDICAL NOTES.

— Professor Graskey of Würzburg has been called to Munich to be the successor of the late lamented Professor Van Gudden.

— The sixth International Congress of Hygiene and Demography, will meet at Vienna in September, 1887, instead of 1886, as originally proposed. Among other subjects the precautions, international or others, to be taken against the propagation of contagious diseases by rags; and the international regulations to be adopted against the adulteration of food products, will occupy prominent places in the discussions. Those who are interested are requested to suggest other subjects, addressing Prof. de Gruber, Brunn, near Vienna.

— Dr. Moxon, so long and prominently connected with Guy's Hospital, died suddenly on the 21st ult. After a hard day's work, including an oral examination at the College of Physicians, prior to returning to his house at Highgate, he went to his consulting rooms in Finsbury Circus, where he was engaged for some time in correspondence. As he failed to return home at his usual hour before midnight, messengers were dispatched to Finsbury about two o'clock on Thursday morning, and Dr. Moxon was found to have been dead for some time, lying in his consulting room. The cause of death is at present unknown, but it is supposed to have been due either to apoplexy or to heart disease.

— Instances of extreme old age are reported from Russia. The *Novosti*, a Russian journal, announces the death, in the almshouse of St. Petersburg, of a man aged one hundred and twenty-two years, who had been an inmate since 1818. His mental faculties were preserved up to the time of his death, and his general health was excellent to the age of one hundred and eighteen, when he commenced to fail. There is in the same institution a soldier's widow, whose age, as shown by documentary evidence, is at least one hundred and ten years. In our own country, at New Holland, O., Mrs. Arnold has just celebrated the one hundred and ninth anniversary of her birth; and her two sisters are still living, aged respectively one hundred and six and one hundred and twelve.

— An English contemporary cites a striking instance of the vexatious quarantine restrictions, which prevail in some countries, as afforded by a correspondence, recently presented to Parliament by the Foreign Office, relating to the brigantine *Maggie*, of London, which was called upon, on its arrival at Fayal, to undergo a quarantine of five days, but allowed to discharge her cargo in a lazaretto, the Portuguese authorities having declared Great Britain "suspected" of cholera. Having proceeded to Terceira, the officials there, regardless of the quarantine she had already undergone at Fayal, refused to allow her pratique, and the vessel was relegated to Lisbon. The Foreign Office, recognizing the importance of the case, and supporting the owners' claim for one hundred pounds for the loss sustained, opened communications with the Portuguese Government, through Mr. Petre, Her Majesty's Minister at Lisbon; but no reply was vouchsafed for eighteen months, when the Portuguese Government expressed their opinion that the stringent measures adopted did not constitute any violation of the law, and refused to admit the claim.

NEW YORK.

— The corner-stone of a new infirmary for the Five Points House of Industry was recently laid with appropriate exercises. The building, which will be ready for occupancy in October, is to be four stories nigh, and will have a frontage of twenty-five feet and a depth of eighty feet; with accommodations for about eighty patients. The erection of this infirmary was rendered necessary by an act of the Legislature, passed at the last session, requiring children suffering from infectious eye-disease to be isolated.

— Dr. E. F. Brush, Health Officer of the town of East Chester, in West Chester County, who has lately

[1] Amer. Journ. Med. Sciences, October, 1882.

been engaged in investigating a number of cases of pleuro-pneumonia which have occurred among the cattle of that town, has made a report to the Board of Health, in which he expresses the conviction that the disease originated among the stock of the Mount Vernon branch of the New York Infantile Asylum, which is situated in the same country. The cows there became diseased, so that their milk was unwholesome, and (what seems a most extraordinary procedure on the part of those in charge of the institution), the animals were then sold off at auction. By order of the Health Officer, nearly all the diseased cattle were subsequently killed. The matter is to be reported by the Board of Health to the Grand Jury of the county at its next session.

Miscellany.

DEATH FROM CHLOROFORM.

LADY FLORA WILMOT died at Swansea, England, after taking chloroform in a dentist's chair, for the extraction of a tooth. The anæsthetic was administered by a physician. The patient had taken chloroform twice before without any bad effects. In all, but two drachms were used. All attempts to restore the patient by the use of nitrite of amyl and artificial respiration were of no avail. The physician remarked immediately after the extraction of the tooth, "I hate giving chloroform for you dentists, because you will have your patients sitting up." Both the dentist and the physician were exonerated by the jury which was called to hold an inquest. *Science* comments on this case as follows: "The evidences of the danger in the administration of chloroform are so overwhelming, except in a few cases, that no one is justified, at the present day, in using it in so simple an operation as the extraction of a tooth; and a jury would be doing its full duty in holding responsible for the death of the patient any physician or dentist who administered it in such a case, with a fatal result."

TOILERS AMONG THE DEAD.

AT a recent meeting of the Academy of Medicine, M. Brouardel made known some curious and interesting facts concerning the dead body of a girl, aged twenty-two, which was discovered in a cellar under a heap of straw. The body had lain there about a year, and was in a perfect state of mummification. One of the limbs was shown at the meeting; it was thoroughly dessicated; the tissues were hardened, and gave a sound when struck. MM. Brouardel and Andouard attribute this mummification to the dryness of the soil on which the dead body had been placed; but the most important factors were five different species of acarina which deposited the *débris* of the envelopes of their eggs and carapace among the dust that covered the dried tissues of the body. M. Mégnin has proved that, by studying the generations of acarina which have been at work on a dead body, the date of death can be ascertained. This entomologist, by examining the *débris* of acarina in a child's corpse, ascertained that death occurred two years previously; and a judicial inquiry confirmed this statement. M. Brouardel described the order of succession of the different species of acarina which worked on the dead body of the young girl, also the work of destruction accomplished by each separate species: the gentles (larvæ of flies), *dermestes*, *sarcophagus*, *latierus*, and *lucina cadaverina*. One species absorbs the fluids, another consumes the fatty acids. When a species has finished its work, it dies on the dead body, or is devoured by a succeeding species. Each generation in summer-time lives from six weeks to two months. In a recent case of murder M. Mégnin established with precision the exact date of the burial of the human remains discovered in the garden. Among the remains, a particular kind of ant was observed, which is never found in soil recently disturbed; also the *débris* of acarina, known as *Œsophagus echinococcus*, which also furnished a chronological indication; portions of a bulb of a lily furnished further proof. Two years must have elapsed in order that the bulb should undergo the alterations it presented. M. Brouardel dwelt on the value of these entomological data in reference to medical jurisprudence. — *British Medical Journal.*

INCUBATION OF TYPHOID FEVER.

A CORRESPONDENT writes as follows to the *Lancet* regarding a series of cases in which the minimal period of incubation of typhoid fever was known. Two children left their home in the country to come to a London boarding-school on January 11th. On January 27th the younger of the two sickened with typhoid fever. It was then discovered that at the village where they lived there was quite an epidemic of typhoid, and that the water-supply of the house had become contaminated. The school-master at once wished to know at what date it could be definitely said that the elder boy had not contracted the disease. Wishing to be quite safe in my prognosis, I replied that, although it was impossible to say exactly, if he remained quite well at the end of three weeks and a half, dating from January 11th, he would probably escape. The younger boy was moved from school to a house near, and the master kept a most careful watch over the elder one until the three weeks and a half had expired, at which date he seemed in perfect health. My disappointment was great to find that on February 7th, or twenty-seven days from January 11th, he did not feel quite the thing, and his evening temperature was 100°. Up to this date he had taken his food heartily and was in capital spirits. He later on had troublesome constipation, and died of intestinal hæmorrhage. No other boy in school contracted the disease.

The following is a list of the inmates of this country house who have caught the fever. Where known, I have stated the latest possible date on which the patient could have contracted the disease; of course it may have been contracted much earlier. 1. Younger boy came up to boarding-school on January 11th; recovered; incubation sixteen days. 2. Elder boy came up with No. 1 on January 11th; died of hæmorrhage; incubation twenty-seven days. 3. A sister left home on January 21st to stay with friends; recovered; incubation nine days. 4. A brother left home on January 14th to stay with friends; recovered; incubation sixteen days. 5. The nurse of No. 4; recov-

ered. 6. Cook who lived at the country house and stayed there throughout; recovered. 7. A servant, who come up from country house, and being taken ill was sent to a cottage hospital near, where she was said to be suffering from scarlet fever and sent on to fever hospital, but on inquiry I found it was a simple case of typhoid; recovered.

Correspondence.

TOXIC EFFECT FROM PERMANGANATE OF POTASSIUM.

MR. EDITOR,— I have noticed lately one or two references in your JOURNAL to the use of the permanganate of potassium internally in amenorrhœa and would like to give my own experience and that of my partner.

In the case of a girl of nineteen with advanced phthisis and amenorrhœa of ten months standing, I administered the permanganate in two-grain capsules t. i. d. for two days, which was followed on the evening of the second day by a moderate flow lasting for two or three days. After this the girl's general health improved slightly and the flow appeared the following month just as previous to the commencement of the lung trouble. Subsequently, however, she failed rapidly and died in about two months. My partner, Dr. Brock, on hearing of the success in this case and also that a young married lady had taken five and six grains at a dose, and had had one or two miscarriages while following this treatment under another physician, prescribed two-grain capsules of the permanganate for a young lady, unmarried, twenty-two years of age and somewhat debilitated, who had been suffering from amenorrhœa for four or five months. After the first dose she complained of severe burning pain from the throat to the pit of the stomach, was nauseated, pulse rapid and rather weak. This was supposed to be due to some irritating article of diet and the patient drank a quantity of milk which eased the pain somewhat. The next morning when she took the second capsule there was a repetition of the symptoms of the previous evening, only more severe. The patient was intensely nauseated and vomited, complained of intolerable burning in the stomach and throat, was almost pulseless, completely prostrated and did not fully recover for two or three days.

Subsequently, in the case of another young lady, unmarried, and about the same age and condition of health, who had suffered from suppression of the menses for two months, he prescribed one-grain capsules with the same result, pain like a flaming fire in the stomach and throat and generally symptoms of shock and collapse.

Since then neither of us has prescribed permanganate of potassium internally. Wood, Stillé, and all the authors I have consulted, fail to make any mention of toxic symptoms from the internal administration of the drug.

Are the symptoms due to the rapid decomposition into potassium and the binoxide of manganese?

Before the drug is too freely prescribed in full doses its toxic action should be more carefully investigated and better understood. Yours truly

W. D. BIDWELL, A.M., M.D., (HARV.)

LEAVENWORTH, KANSAS.

REPORTED MORTALITY FOR THE WEEK ENDING JULY 31, 1886.

Deaths reported 3,226: under five years of age 1,683: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 1,115, diarrhœal diseases 825, consumption 371, lung diseases 160, diphtheria and croup 100, typhoid fever 61, whooping-cough 39, scarlet fever 29, measles 32, malarial fever 16, cerebro-spinal meningitis 12, erysipelas two, puerperal fever two. From whooping-cough, New York 17, Brooklyn six, Chicago four, Philadelphia and Pittsburgh three each, Baltimore two, Boston, St. Louis, District of Columbia, and Charleston, one each. From measles, New York 14, Chicago six, Pittsburgh four, Brooklyn, Boston, Charleston two each, Nashville and Salem one each. From scarlet fever, New York 10, Pittsburgh five, Chicago and St. Louis four each, Philadelphia two, Brooklyn, Baltimore, District of Columbia and Fall River one each. From malarial fever, Brooklyn seven, Baltimore four, New York and Philadelphia two each, Nashville one. From cerebro-spinal meningitis, New York four, Chicago and Springfield two each, Baltimore, St. Louis, Worcester and Northampton one each. From puerperal fever, Baltimore and Pittsburgh one each.

In the 21 cities and greater towns of Massachusetts, with a population of 1,006,508 (population of the State 1,941,465), the total death-rate for the week was 26.39 against 24.27 and 21.27 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,033,817, for the week ending July 17th the death-rate was 19.7. Deaths reported 3,425: infants under one year of age 1,107: acute diseases of the respiratory organs (London) 167, diarrhœa 411, measles 93, whooping-cough 50, scarlet fever 41, fever 39, diphtheria 17.

The death-rates ranged from 12.1 in Brighton to 24.8 in Manchester; Birkenhead 14.8; Birmingham 16.2; Bradford 20.5; Hull 13.9; Leeds 14.9; Leicester 19.1; Liverpool 18.9; London 21.1; Nottingham 18.7; Sheffield 17.8; Sunderland 16.8.

In Edinburgh 18.2; Glasgow 21.8; Dublin 19.7.

The meteorological record for week ending July 31, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, July 31, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 31, 1886, TO AUGUST 6, 1886.

MIDDLETON, PASSMORE, major and surgeon. Granted leave of absence until September 10, 1886. S. O. 100, Division of the Atlantic, August 5, 1886

WHITE, R. H., captain and assistant surgeon. Ordered from Angel Island, Cal., to San Diego Barracks, Cal., relieving Capt. Leonard Y. Loring, assistant surgeon. S. O. 64, Department of California, July 28, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING AUGUST 7, 1886.

RUSH, CHARLES D., passed assistant surgeon. Detached from the Receiving Ship, "Franklin," and ordered to the United States Steamship "Pinta."

WILLSON, W. G., passed assistant surgeon. Detached from the United States Steamship, "Pinta," ordered home and wait orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE HOSPITAL SERVICE FOR THE WEEK ENDING JULY 31, 1886

LONG, W. H., surgeon. Granted leave of absence for fifteen days, July 30, 1886.

SAWTELLE, H. W., surgeon. To proceed to Portland, Ore., and Port Townsend, W. T., as inspector, July 29, 1886.

DEVAN, S. C., passed assistant surgeon. Granted leave of absence for ten days, July 26, 1886.

FATTIC, J. B., assistant surgeon. Granted leave of absence for twenty-nine days, July 26, 1886.

SOCIETY NOTICE.

AMERICAN DERMATOLOGICAL ASSOCIATION. — The tenth annual meeting of the American Dermatological Association will take place at Greenwich, Conn., on August 25th, 26th and 27th, 1886, and the following papers will be presented:

Address by the President, Dr. Edward Wigglesworth: 1. "Report of a Case of Lymphadenoma (Mycosis Fongoide) and Autopsy," Dr. G. H. Fox. 2. "Note Relative to the Bullous Eruption occurring after Ingestion of Iodine Compounds," Dr. J. N. Hyde. 3. "Erythanthema Syphiliticum," Dr. E. B. Bronson. 4. "Rötheln," Dr. I. E. Atkinson. 5. "Precocious Gummata," Dr. R. W. Taylor. 6. "Clinical Notes on Scabies," Dr. F. B. Greenough. 7. "Clinical Observations regarding the Value of Resorcin, Icthyol, and Lanolin in Cutaneous Diseases," Dr. H. W. Stelwagon. 8. "Trophoneurosis of the Skin," Dr. G. H. Tilden. 9. "Native Plants Injurious to the Skin," Dr. G. C. White. 10. "Cartilaginous Tumors of the Skin," Dr. A. R. Robinson. 11. "A Few Additional Notes on Psorasis," Dr. F. B. Greenough. 12. "Report of a Case of Exfoliative Dermatitis," Dr. W. A. Hardaway. 13. "A Clinical Study of Scleroderma," Dr. J. E. Graham. 14. "A Case of Carcinoma Cutis," Dr. L. N. Denslow. 15. "Keratosis Follicularis." Dr. P. A. Morrow. 16. "Surgical and Obstetrical Scarlatina," Dr. I. E. Atkinson. 17. "Notes on Drugs," Dr. H. G. Piffard. 18. "Two Cases of Dermatitis Herpetiformis," Dr. A. Van Harlingen. 19. "Remarks and Queries on and as to Relative Frequency of Moles and their Pathological Changes on the Head and Face," Dr. S. Sherwell. 20. "An Unusual Form of Tuberculosis of the Skin," Dr. G. H. Tilden.

EDWARD WIGGLESWORTH, M.D., *President.*
(per G. H. T.)
G. H. TILDEN, M.D., *Secretary.*

DEATH.

Dr. Calvin Seavey, of Bangor, Me., died suddenly on August 1st, aged seventy-seven. He was graduated from the Medical School of Maine in 1857.

BOOKS AND PAMPHLETS RECEIVED.

The Refraction and Accommodation of the Eye and Their Anomalies. By E. Landolt, M.D., Paris. Translated under the author's supervision, by C. M. Culver, M.A., M.D. With 147 illustrations. Philadelphia: J. B. Lippincott & Co. 1886.

Intubation of the Larynx for Diphtheritic Croup. By E. Fletcher Ingals, A.M., M.D., Professor of Laryncology, Rush Medical College; Professor of Diseases of the Throat and Chest, Woman's Medical College, Chicago. Presented to the Chicago Medical Society, June 21, 1886. (Reprinted from the Journal of the American Medical Association, July 10, 1880.) Chicago: Printed at the Office of the American Medical Association. 1886.

THE MANAGEMENT OF CASES OF RIGIDITY OF THE OS UTERI IN LABOR.[1]

BY WILLIAM E. BOARDMAN, M.D., OF BOSTON.

A CORRECT appreciation of the condition implied by the term *rigid os uteri*, is a necessary preliminary to its proper management. Many practitioners, indeed some obstetric writers, failing to distinguish between cause and effect, have confounded different conditions of tedious labor where dilatation occurs with abnormal slowness. The os may be soft, yielding, *dilatable*, and yet it may dilate very slowly, or its dilatation may stop entirely, for a longer or a shorter period, from a variety of causes, but it is a misapplication of the term to say of these cases that rigidity of the os or cervix is present and obstructs labor. For instance, quoting from Bedford,[2] "it will occasionally happen that the os uteri does not respond to the efforts of the uterus, the contractions recur at intervals, but they have not sufficient force; the patient becomes wearied with the abortive efforts of nature; her strength gives way, and the nervous system is much disturbed. Here, then, is a condition of things which must not be misapprehended — do not mistake it for rigidity of the os." A similar caution might be enjoined with reference to many other complications of the first stage of labor, among which I may mention obliquity of the uterus, faulty positions and presentations of the fœtus, abnormalities of the fœtus and of the pelvis, hydramnios, constriction of the cervix from compression between the fœtal head and pelvic brim, constriction and hypertrophy of the anterior lip. In these cases, to be sure, rigidity may also occur as a coincident or secondary complication, but, in themselves, they are not usually a cause of this condition; they may, and commonly do occasion delay in dilatation, but they do so merely because they complicate the normal process of labor, but, as soon as the specific complication is overcome by the efforts of nature or by appropriate treatment, dilatation may go on without interruption. In other words, the imperfect dilatation, as a rule, is merely the negative result of these abnormal conditions to which we have referred.

True rigidity, on the contrary, should imply an *undilatable* condition of the os — and this is to be understood in a relative, and not an absolute sense — where dilatation does not ensue, or occurs with abnormal slowness, or is arrested, on account of certain accidental conditions arising at the time of labor — of congenital defects of formation, or acquired physiological or pathological deviations in the structure of the cervix. In these cases, only, the undilatable os is truly rigid, and becomes an efficient cause of delay to labor, and this obstruction may persist, under certain circumstances, so long as to endanger the mother or child, or both together.

The scope of my paper obliges me to omit the consideration of those cases where the dystocia is due to radical defects of development, to complete atresia, and to pathological changes incident to malignant and fibroid disease of the cervix, which often require special methods of treatment, perhaps peculiar to each individual case, and to restrict myself to the discussion of the more common ones to which reference has been made, including spasmodic stenosis, the most usual form in primiparæ, and rigidity from simple pathological changes which appertain to cicatricial, hyperplastic, or hypertrophic induration, and, as a rule, are met with only in multiparous women.

Actual labor, I need not remind you, is commonly divided into three stages, with the first of which only, the period of dilatation, have we to do at present. Strictly speaking, this comprises the entire period occupied in the expansion and retraction of the cervix, and the full dilation of the os uteri. For clinical convenience, however, it is customary to await until the cervix is "taken up," as it is termed now-a-days, before it is considered that labor is imminent. So that, other factors being normal, our attention, at first, is largely directed to the os in estimating the probable character and duration of the labor.

In what may be called normal labors, the length of this first stage varies considerably, according to different circumstances which it is unnecessary for me to enumerate at this time, and it is generally conceded that, so long as the os continues to dilate, however slowly, the membranes are intact, and no extraordinary accidents or emergencies threaten or occur, we are not called upon to abbreviate it in any manner, except indirectly in the way of husbanding the maternal strength by the various methods which are in common use for promoting rest and refreshment, furnishing adequate nourishment, and providing for the due performance of the various ordinary functions of the body.

In such labors this stage may continue for days, and yet with proper attention to these points, neither the mother nor her child may be exposed to any serious injury; the labor may become "tedious," but not "laborious," which latter term properly implies danger in a greater or less degree.

Not infrequently, while all the other factors of normal labor in the first stage occur, delay ensues, which, upon examination, is found to be due alone to the condition of the os itself: it is unyielding and rigid — sometimes thick, hard, and muscular to the feel, at others thin, wiry, like cartilage or parchment, or swollen and œdematous. Even in these cases, except, perhaps, in some few instances of notable cicatricial degeneration, so long as the membranes are unbroken, and the os is pressed upon by the fluid sac during the continuance of the pains, which are intermittent in character, interference is rarely demanded, for the cushion or fluid can do no harm to the cervix, and the fœtus cannot be subjected to undue pressure at any part, for everywhere it is protected from insult by the fluid with which it is invested.

Sometimes, however, it will be observed that, during the pains, the head impinges directly upon the lowest segment of the cervix, so that no bag of waters is formed, and, if the os is rigid, the irritation to which it is subjected by the immediate pressure of the fœtal part, will tend to augment the rigidity, especially in a primipara. If such a condition of things be found, speedy relief may often be afforded by pressing up the presenting part and allowing a quantity of fluid to collect in front of it.

In either of these cases, whenever we meet with an unyielding os under the pressure of the fluid sac, and other factors are normal, it is the rule that the pains tend to become abnormal in character, irregular, short and cramplike, or continuously severe; the patient

[1] Read at the Annual Meeting of the Massachusetts Medical Society, June 8, 1886, and recommended for publication by the Society.
[2] Principles and Practice of Obstetrics, 5th Ed, p. 362,

soon exhibits symptoms of nervousness, perhaps anxiety and irritability, and, if not properly treated, her general and uterine strength will be wasted, to her detriment, probably, in the later stages. Anodynes administered to such patients usually will forestall or control these unfavorable symptoms, and a sleep, more or less prolonged, will be followed by a renewal of strength and courage, and, generally, by a more dilatable condition of the os.

In many cases, however, where the os early shows a disposition to rigidity, an accident occurs which most surely leads to an increase of the dystocia — namely, the premature rupture of the membranes. In other cases, this accident obviously is the prime cause of the rigidity, and, in either instance, we are quite sure to have to do with a laborious labor, which will be the source of much suffering, and even danger, to the mother, and of peril to the child, and, too, of annoyance and anxiety to the physician. Fortunately, with judicious care, and under ordinary methods of treatment, most of these patients ultimately do well, and the mother is safely delivered of a living child.

Probably reasoning from this fact the cardinal rule has been transmitted to successive generations, to abstain from manual or instrumental interference in these cases, and to content ourselves and endeavor to satisfy our patients simply with, what often are merely palliative measures, nauseants, emetics, depletion, general and local anodynes, and to await the favorable issue of this stage or the occurrence of dangerous symptoms in the mother or the death of the fœtus. Until comparatively recent years every kind of interference was deprecated, so long as the fœtal life persisted, and, indeed, craniotomy on the living child has been advised and practised by some in the interest of the mother, and this fact led to the scathing criticism by Lovati, of Pavia, who said, "in England they do not hesitate to kill the child, not only in order to save the mother from the danger of the Cæsarean section, but even to spare her the suffering of the simple application of the forceps." Some obstetricians, writing a century and more ago, advocated, while others of later date have sanctioned or timidly subscribed to, the practice of making longitudinal incisions or scarifications of the cervix in cases of rigidity, where threatening symptoms ensue which do not yield to the common methods of treatment. Indeed in more recent and even modern times, such eminent authorities as Velpeau, Kilian, Martin, Scanzoni, Simpson, Murphy and others have given their assent to this dangerous procedure. Concerning this operation Ramsbotham[3] wisely observed, "I should consider it as one of those exceptional modes of treatment which surgeons are sometimes driven to undertake, in consequence of encountering some extraordinary difficulty, not provided for by the legitimate and established rules governing surgical science." Carl Braun[4] states that the field for this operation is extremely limited, and the necessity cannot occur more frequently than once in fifteen thousand labors. The discussion of this method of practice Lusk,[5] very properly in my opinion, dismisses in a very cursory manner with the following words:— "I have purposely avoided making mention of incisions through the vaginal portion of the cervix, as, in a large experience in difficult labors, I have never so far seen the occasion for their employment," though in his chapter on the forceps he introduces this paragraph[6]:— "In cases where it is necessary to expedite delivery, the resistance of the incompletely dilated os may be overcome by a number of incisions about one-fourth of an inch in depth, made with a blunt-pointed bistoury passed between the cervix and the child's head," adding, "it is very rare, however, that this otherwise trivial operation is really called for."

Contenting myself with this brief reference to the ordinary and extraordinary traditional modes of treatment in these cases, permit me to state, in a few words, the prevailing methods, at least I believe among the most competent practitioners in this country, which, perhaps, are described by no writer more intelligently and tersely than by Lusk, while they are more extensively catalogued by Atkinson.[7]

Premising that the abnormal factor we have to deal with is the rigid os, a stenosis from spasmodic rigidity or due to what I have termed simple pathological changes in the structure of the lower segment of the cervix, in which cases, too, the spasmodic action becomes a prominent feature, the first endeavor is to annul the sense of pain and to restore the disorder of the nervous system, so as to induce relaxation of the spasm, and to foster the maternal strength. This end is sought in different ways, largely by the administration of opiates, but more generally by the use of anæsthetics or of chloral, alone or in succession. In some instances, with multiparous women, where the rigidity appears not to be extreme, external frictions of the uterus and oxytocics are admissible, and among the latter quinine, perhaps, is the safest and best. Ergot, on the other hand, is rightly considered a dangerous agent at this stage for many reasons, nor is Kristeller's method of expression applicable, except in rare cases, until a later period. Electricity has been warmly recommended again of late. Judiciously applied it is said to relieve spasmodic action, to promote dilatation and to increase the regularity and efficiency of the pains. Vaginal and rectal injections of simple hot water or medicated solutions are frequently employed, and apparently with benefit in some cases. Hip baths, also, are serviceable, but generally inconvenient. The local application of belladonna in the form of ointment, I think, is now rarely employed. Not unlikely cocaine will prove to be an important adjunct to our measures for the relief of these cases. Amyl nitrite and atropia, also, have lately been recommended, as efficient agents for relaxing a spasmodic condition of the os. Venesection is rarely employed in these days, and the same may be said of nauseants and emetics, though formerly, of course, much reliance was placed upon all of these. When the os is sufficiently dilated to admit the introduction of the forceps, it is the practice of some eminent obstetricians, notably of Dr. Johnston, of Dublin, to employ this instrument at an early period, and Dr. I. E. Taylor has devised a long, narrow bladed pair of forceps for this purpose, which is said to be capable of introduction through a cervix measuring hardly one and a half inches in diameter. Artificial dilatation of the os has been advised or suggested by many distinguished obstetricians, from the time of Smellie, if not before, while it has been condemned in unmeasured terms by contemporaneous authorities. Thus

Churchill[8] said of it, "I do not deny that dilatation may thus be effected; but I believe it to be hazardous in skilful hands, positively dangerous in unpracticed ones, and unnecessary in all cases;" and Bedford[9] remarked, "the abominable practice, commended by some of the older writers, of introducing the hand into the vagina for the purpose of distending it (the os uteri), is not for an instant to be tolerated. These rude manipulations can never receive the sanction of the scientific accoucheur." Sir James Simpson[10] however, Dr. James Braithwaite in 1879[11] and a few others of later date, have revived, sanctioned and advised the resort to digital dilatation when the rigidity has persisted so long as to induce symptoms of danger. To Robert Barnes is due the credit of demonstrating the advantages of a *more early* resort to artificial dilatation, a practice which is now generally commended by accoucheurs of the largest experience, but he gives his preference without stint to the use of "Barnes' bags" for this purpose. Referring to digital dilatation in the form of dystocia under consideration, after describing with some minuteness the technique of the operation, he says[12] "in some cases in which the second stage of labor has advanced, the cervix may sometimes be dilated by the hand, but," he adds in the same paragraph, "what is called manual dilatation of the cervix should be abandoned, except in the case of spasmodic contraction after expulsion of the child — as, for example, when the placenta is retained or clots are filling and irritating the uterus." Lusk, too, gives his entire assent to the early employment of these dilating bags.

While we may not accept fully the specious arguments of Sir James Simpson,[13] which were largely founded upon the dangerous deductions from statistics or be allured by the ponderous logic of Matthews Duncan,[14] experience, if not common sense, seems to teach that the undue prolongation of the first stage, with the abnormal conditions of ruptured membranes and a rigid os, is attended with danger both to the mother and child, and the danger to both is progressive with the increasing duration of this stage. Therefore it is a matter of great importance for us to determine when this stage is becoming unduly protracted, and, for this purpose, we must have regard both for the mother and for her child. Neglect of this common regard has led to the unnecessary sacrifice of human life and to the opprobrium of the obstetric art. It has been too common to delay too long in order to see what nature can endure, rather than to endeavor to determine, as early as possible, how much she can accomplish. Taking this, then, as the theme for my concluding remarks, permit me, by way of introduction, to recite briefly the histories of two cases, which occurred during one of my terms of service as visiting physician at the Boston Lying-in Hospital.

Case I. Addie S., single, twenty-five years of age, primipara, entered January 28th. From the first she was nervous and despondent. She continued to have pretty constant aching pain in the lower abdomen and sacral region, during the expansion and retraction of the cervix, which was not fully "taken up" until the morning of February 7th, when the os was the size of a ten cent piece, thin and unyielding. The head was low down, at the inferior strait, and the pains were moderately severe, with slight intermissions, during that day. At 6.25, P.M., the membranes ruptured. As no progress ensued, chloral was administered at 7, 7.30 and 8, P.M., with no permanent effect upon the os. At 9, P.M., full surgical anæsthesia was induced and continued for several minutes. Chloral was again given at 11, 11.40 and 12.30, P.M., after which the pains became more severe and nearly constant. At 1, A.M., of the following day, the pains were rather more intermittent and moderately severe, but the os showed no change. At 4, A.M., full anæsthesia was induced for four minutes when the os acquired the size of a twenty-five-cent piece. At 6.30, A.M., it was rather larger than a half dollar; the maternal pulse increased from 100 to 125 and the fœtal pulse from 140 to 160. Under this condition of things I was summoned. Learning from the house physician that under the immediate influence of the chloral or the ether the os each time became dilatable for a brief period, but soon recovered its rigidity, I administered two more doses of chloral, and taking advantage of the dilatability which I produced, I easily stretched the os with the fingers, slipped it over the head, applied the Vienna forceps and readily extracted the child, which was asphyxiated, but fortunately resuscitated. The mother, however, shortly after died, evidently from shock and collapse. There was no uterine rupture and no hæmorrhage.

Reviewing the record of this case, it will be observed that the woman presented unfavorable symptoms from the outset; that she was nervous and despondent; that she suffered, more or less, for more than a week, during the retraction of the cervix; that the os was rigid from the commencement of its dilatation; that the membranes ruptured early in the first stage; that the repeated employment of customary means had little effect in promoting dilatation; that twelve hours after the rupture of the membranes the os was only as large as half of a dollar, when symptoms indicating danger to both mother and child supervened; that the resort to manual dilatation, *while the os was made soft and yielding*, enabled me to deliver a living child in a few moments. Its asphyxiated condition, however, I think clearly showed that a little longer delay would have imperilled its life. As it was, I cannot but think that the fatal result to the mother must be attributed, in a measure at least, to the delay in interference, which was especially dangerous considering her protracted mental agony and the prolonged physical suffering which she experienced, though at no time was this notably severe.

Case II. Ella P., nineteen years of age, single, primipara, entered January 22d, at 11.55, A.M., labor having begun at 1, A.M., of the same day, and the membranes had broken at 7, A.M. On entrance the cervix was "taken up" and the os admitted only the finger tip. Pains recurred quite regularly and with no unusual severity, but it was soon determined that there was delay on account of the condition of the os, which, on the following morning, was the size of a half dollar, thick and rigid. Chloral was twice repeated and snoring anæsthesia was induced, but with slight if any permanent effect. At 4, P.M., of this, the second day, thirty-three hours after the rupture of the membranes, the condition of both mother and fœtus before this having been good, the maternal pulse suddenly rose to 110 and the temperature to 102.8°, while the

fœtal pulse increased from 140 to 180. Shortly after this I was summoned, and, finding the threatening symptoms still present, I had the patient etherized, but did not administer chloral beforehand, partly to save time but more because I had in mind that in the previous case possibly the fatal result to the mother might have been promoted by the combined effect of the two agents. While under the influence of the ether, I did not obtain the general dilatable condition of the os which I did in the other case, but the left side dilated readily under the pressure of the fingers, and, having obtained sufficient space, I introduced the forceps,— the head had passed the brim,— and by the combined effects of traction with the instrument and, in the intervals, gradual stretching and pushing up the right side, the os finally slipped over the head, and then the child was quite readily extracted at 6.25, A.M., nearly thirty-six hours after the rupture of the membranes and forty-two after the onset of labor, but it was still-born. The mother made a good recovery.

In this instance, too, I believed I conformed essentially to the general rules of practice which prevail in these cases. The error, in delaying interference too long, or until threatening symptoms supervened, I believe, was the cause of the death of the child, as it was, if not the principal, at all events a contributing factor in occasioning the death of the mother in the first case.

That "meddlesome midwifery" is bad and to be avoided needs no argument at this day, but I submit that, while this expression and the doctrines evolved from it have served a very useful purpose in preventing the indiscriminate resort to manual or instrumental interference, when often it is uncalled for and even unsafe, yet increased experience, I think, rightly teaches me that, in many instances perhaps, we have been controlled too completely by the dictates of traditional practice that have been accepted by successive generations as matters of doctrine which ought not to be questioned, and, with this view, I have come to believe with others that the rule, to await the occurrence of alarming or dangerous symptoms, either in the mother or the fœtus, in these cases where the dystocia is due primarily or essentially to the rigidity of the os, is an excess of conservatism which tends to disaster, as already observed, either from violence done to the mother, or from injury to the child in consequence of the great and direct pressure to which it is exposed for so long a period after the escape of the amniotic fluid or on account of its being deprived of proper and sufficient nourishment by the interference with the utero-placental circulation. Accepting this proposition it is our duty to abbreviate this stage, in these cases of dystocia, so far as we are able to do it.

Referring to the success which has resulted in other forms of dystocia from the practice of manual dilatation, notably with placenta prævia and eclampsia and in the induction of premature labor, as suggested many years ago, even by Hippocrates and Celsus, in some circumstances,[15] but revived and popularized in this country, I think, at all events in this vicinity, by our esteemed associate, Dr. A. D. Sinclair, and also to the now well-recognized effect of chloral and deep anæsthesia for a brief period in bringing about a dilatable condition of the os,— not to mention some other agents which have been employed for a similar purpose,— I believe we not only have it in our power, but that it is our duty, in these cases of tedious labor which promise to become laborious, to afford timely relief by early interference, as soon as we are satisfied that nature unaided directly by art is not likely to accomplish delivery with safety, by following up the temporary dilatable condition, which we can induce by the use of chloral and like agents, with manual dilatation, and the subsequent use of extracting means if they appear then to be required — that is to say, before dangerous symptoms occur.

If the head be above the brim or not far advanced, and the contractions are not too frequent and severe, the early introduction of the hydrostatic dilators of Barnes will, perhaps, accomplish everything that is required; but these are always open to the objection that, even in the most skilful hands, they are insensible and one is liable to effect dilatation with them too forcibly and too rapidly, and so start a laceration of the cervix which may end in extensive rupture. Fortunately, however, if we may rely upon recorded cases, this accident is not a common occurrence. My experience confirms that of many others, that, in a large number of these cases, the presenting part impinges so forcibly upon the os and is so firmly invested by the tissues below the "contraction ring," that the bag cannot be inserted within the os without the exercise of so much manipulation and force as to do violence to the tissues, and, furthermore, in many cases it is found impossible to keep the bag in position, — it will inevitably slip out before dilatation can be effected by it.

With manual dilatation, the principle is the same as with the hydrostatic bag, but employing the former we have the advantage of the tactile sense, which enables us to guide and control the process with the utmost precision and hence with due regard to the integrity of the maternal parts.

When the head has passed the brim and entered the excavation, the waters having escaped, I believe there can be no question as to the choice between these two methods of artificial dilatation, and we should resort without hesitation to the use of the fingers to accomplish the desired object.

I have already alluded to the practice of incising or scarifying the os for the purpose of expediting delivery in these cases under consideration, where no disproportion exists and the dystocia is dependent solely upon the rigid, unyielding condition of the os, whether this is a spasmodic stenosis alone, or associated with the cartilaginous condition which is the product of a cicatricial process, a hyperplasia or hypertrophic induration. All authorities agree that this necessity occurs with extreme rarity. My experience, to be sure, has not been very extensive, but I have never met with, nor have I known of, a case where this procedure became necessary. Indeed, I do not believe it is ever demanded, except in cases of absolute atresia or occlusion of the os, for employing anæsthesia, chloral, and like agents, and artificial dilatation *together*, I feel sure we have it in our power to accomplish delivery, even in the extreme cases of simple pathological degeneration of the cervix, without exposing the uterus to the imminent danger of extensive rupture.

With regard to the proper time when the interference of art is demanded, the essential point is to anticipate the period when dangerous symptoms will occur. As before remarked, while the membranes are intact, rarely will we be called upon to interfere, for,

[15] Vide Braun, op. cit. p. 763.

in these cases, there is practically no danger— nature is equal to the emergency and the patient's endurance is not by any means put to the utmost test.

When, however, the membranes have broken prematurely and the amniotic fluid has escaped, and, I may add, this is the rule in the pathological states of the os to which I have just alluded, and we are satisfied that we have to do with a rigid os, recourse should be had, first of all, to the faithful trial of the ordinary means for promoting a continued dilatable condition. These having been fairly tried, but without success, we should at once resort to artificial dilatation, having first administered an opiate, or better, chloral, either alone or in conjunction with anæsthesia, in order to develop a temporary yielding condition. This latter procedure, I repeat, I offer as an important and essential factor to the easy and safe performance of the mechanical process which we seek to effect by the dilating efforts we decide to employ.

Following these methods of practice which, I have endeavored to show, are based upon sound common sense, regard for the well being of our patients and respect for the obstetric art, I believe we shall be more successful in avoiding unnecessary suffering and in saving human life.

A DISCUSSION OF THE STATISTICS OF OVARIOTOMY.[1]

BY J. C. IRISH, M.D., OF LOWELL.

Of all the major surgical operations, ovariotomy has received the greatest attention with regard to its statistical results. The reason for this is very apparent when we recall its early history. It was an operation very bitterly condemned and assailed by the profession at large at the time of its first performance by McDowell, and for many years after.

Those who believed in its promise of usefulness presented to its opponents their lists of lives saved from a disease otherwise hopeless, and usually soon fatal, as an unanswerable argument in its favor. Although these statistics have long since silenced all question as to the propriety of ovariotomy, still the prominence given them has continued and increased, so that, to-day, the ovariotomist, as a rule, simply presents to the profession his number of operations and the percentage of recoveries, as representing in an exact measure his skill in making the operation, and his wisdom in the details of after-treatment.

The various conditions that determine the result of an ovariotomy, and, at the same time, are beyond the control of the operator, are so much in the background, that the unsuccessful cases gives the profession and the surgeon as well, the feeling that there must have been some fault of omission or commission on his part. That is, such prime importance has been given to the bare statistics as almost to persuade one that the skill of the operator alone is the sole factor in determining the result, and that an ovariotomist of perfect skill and wisdom would save every case. The effect of this tendency to regard the operator as entirely responsible for every unfavorable result has been to stimulate him to the most careful study of every detail of the operation, and, in consequence of this care, the modes of operative procedure have become well-nigh perfect.

[1] Read before the Section of Obstetrics and Gynæcology, Suffolk District Medical Society, May 19, 1886.

This weight of responsibility loaded upon the shoulders of the ovariotomist has contributed, therefore, to his success. It may also have had its effect, not quite so salutary, upon the statistics that have been recorded. It is not unreasonable that the specialist in abdominal surgery, where every failure, in a certain way, reflects upon his skill, and is charged up to his discredit, should present his statistics in the most favorable light that they can bear. Cases in which he may have avoided an operation can be omitted; also those cases of incomplete operation: that portion of his entire list which gives the best percentage of recovery may alone be published.

In other fields of surgery, and in medicine as well, the unreliability of statistics is conceded; but in ovariotomy, for the reason I have given, they are, perhaps, more at variance with the actual results than in the case of other operations. "Statistics alone seldom prove anything, certainly they never explain anything," says Lawson Tait. This, I believe, is not quite true, and, although I am criticising the statistics as not always representing the full proportion of deaths to the recoveries in abdominal surgery, yet I believe they are sufficiently affected by the real results to afford absolute proof of the rapidly-increasing success of ovariotomy.

At the present time, the statistics of ovariotomy in America, when compared with those of our English cousins, seem to show a very decided balance in their favor. One possible reason for this may be that comparatively fewer men operate there than here, and, consequently, that there is a much smaller proportion of operations by inexperienced surgeons, while those who do operate have a much larger experience than falls to the lot of any American. Another reason, and, I believe, the main one, is this, that every standard text-book, at least, so far as I know, except the last edition of Emmet's work, that has been published in America, and which treats at all of ovariotomy, advises postponement of surgical interference, except tapping — "with rare exceptions, a criminal procedure," says Stilling, and assents Thornton — until the failing health of the patient demands it. While in England, formerly, Dr. Clay, Mr. I. B. Brown, Bryant, Hutchinson and Wells advocated early operation before any failure of the patient's strength was apparent. Mr. Wells, however, in 1872, advised delay until considerable impairment of the general health had occurred. Yet in the last edition of his work upon ovariotomy, and in his later utterances upon this subject, he is in accord again with the prevailing English teaching, which favors early operations. In short, I believe that this difference between the English and American authors, in their recommendations given the general practitioner as to the proper time for ovariotomy, has, in great measure, determined the difference in the statistics of the operation in this country and England.

While admitting that in no other operation does so much depend upon the skill, experience, and care of the operator as in this, still it may be worth our while to consider briefly some of those conditions, independent of the surgeon, that may make a disastrous result inevitable. Taking the ovarian cases together, as they present themselves to the ovariotomist, in this country, at least, a certain proportion of them will be found to have in themselves an element of essential fatality. That is, the moment these cases are subjected to operation, they become necessarily fatal, and that,

too, in spite of all care and skill in the performance of the operation, and independently of all accidents that may come at the time of it or afterwards. Every ovariotomist, unless of very limited experience, cannot fail to recall one or more cases of his own that belong to this class, which I have designated as essentially fatal. Cases in which he found conditions of the tumor or patient, or both, such as would necessarily determine an unfavorable issue of the operation — cases in which the ideal operator of perfect skill would have been equally unfortunate. Prominent among the conditions that, in many instances, render an operation essentially fatal, may be mentioned degenerative changes in cyst-walls, cyst-contents, or in the pedicle; twisting of the pedicle, extensive adhesions, particularly within the pelvis, depression of the patient's vitality by septic poisoning, by tapping, by long continuance of the disease, or by the malignant character that the cystoma often acquires.

I have operated in two cases of degenerate cyst-contents, attended, also, with parietal, intestinal, and pelvic adhesions, and with a marked septic condition in each patient. The first case, which recovered, was reported in the *Boston Medical and Surgical Journal* in April, 1884. The second I now briefly refer to in illustration of those cases necessarily fatal on account of the conditions mentioned:

Mrs. F., Pepperell, Mass., age forty. At the time of examination, June, 1884, an apparently solid single tumor occupied the entire abdominal cavity and was firmly impacted in the pelvis. The uterus was held immovably fixed in its position; its cavity of normal length. The case was supposed to be one of uterine fibroma. Patient's temperature 102°, pulse 100. Heart's action feeble, vomiting persistent. An operation was discouraged, more on account of the patient's general condition, than for the reason that the growth was supposed to have been of uterine origin. Two weeks later Mrs. F.'s condition had sensibly improved. With the assistance of Dr. Benoit, Heald, Fletcher, Spaulding and Hartwell, I made an abdominal section and removed two ovarian myomata, which had grown, each from the corresponding ovary, and were so closely joined to each other as to give the impression of a single ovoid growth. Except a small cavity in each filled with pus, they had the firm consistence and structure usual to fibroids. They weighed about [illegible] pounds each. Both were adherent to the [illegible] such it [illegible] of [illegible], the intestines, and the pelvic peritoneum. Very little blood was lost in the separation of the extensive adhesions and the operation was completed as quickly as possible, occupying only about fifty-five minutes. Yet directly after, the patient died from shock. Had this case been in hands much more skillful and experienced than mine, I am sure the result could not have been different. In a word, it was a case with inherently fatal conditions.

In one case with a degenerate pedicle, when the cyst contents were being drawn off with a trochar, a profuse hæmorrhage within the sac, replaced with blood, the liquid removed from the tumor, and, although arrested, as soon as it appeared, the loss of blood was sufficient to cause a fatal syncope. In this instance neither experience nor skill of the operator could have availed in anticipating or checking this fatal hæmorrhage. The element of fatality existed in the patient.

In two cases of extensive parietal visceral and pelvic adhesions, in which I have operated one recovered and the other died. Whether the latter was a case necessarily fatal in itself, or one that might have been saved in the hands of a more experienced and skilled ovariotomist, I cannot say.

In that class of cases, which may be denominated as uncomplicated, simple and recent, and recent cases with rare exceptions are both uncomplicated and simple, I have operated fourteen times with thirteen recoveries and one death. This case I have previously reported. The unfavorable result was, by reason of an accident during the operation, and in a way, the fault of the operator.

For the purpose of making an approximate estimate of the proportion of essentially fatal cases in a large number of ovariotomies, I have collected the reports of six hundred operations by thirty-three different operators, mostly American. These are all cases that have been reported within the past five years, although the operation was performed in some instances somewhat earlier than five years ago.

I have confined myself to these recent operations, because they would contain the smallest proportionate number of deaths from accidental causes, certainly much smaller than the earlier statistics of American ovariotomy would include.

While, of course, it is utterly impossible to make any very exact computation of the number of essentially fatal cases in the list of six hundred, yet an examination of the conditions as existing in very many of those that were unsuccessful, convince one that no mean proportion of them were of this character.

In the entire number there were seventy-five cases of extensive adhesions within the pelvis and elsewhere; of these thirty-three recovered, forty-two died. Although the complete statistics of the different ovariotomists, whose records I am making use of, vary very widely, still in this class of cases, their results are quite nearly uniform. One, reporting the largest number of cases of pelvic adhesions, lost one-half; another eleven out of nineteen; another five out of nine. Therefore, if the most skillful and experienced operators lose rather more than one-half of this class of cases, that is, those with extensive pelvic adhesions, we may very fairly conclude that, at least one-half of [illegible] these essentially fatal, and may place thirty-seven [illegible] proport[illegible] the seventy-five in this category.

Fifty cases of the six hundred were attended with degeneration in some form, of the cyst-walls, of the cyst-contents, or of the pedicle. Nearly all of them were still further complicated by adhesions.

It would seem, too, whenever degeneration, resulting especially from the mature age of the tumor —from its senility— commences with the usual inflammatory action, that, at the same time a great tendency to the formation of adhesions is developed.

Of the fifty cases twenty-six died, and twenty-four recovered. In this class, too, as in the preceding, the results of different operators were nearly the same. No matter into whose hands the patients with degenerate cystomata came, about one-half of them died. So in this second class, we have, practically, twenty-five cases essentially fatal. In the above class are included fourteen cases, that had been tapped, some of them a large number of times, before the operation. Five recovered, nine died. There were eight of these cases, in which the general septic condition before the operation was marked, in which there was considera-

ble elevation of temperature and acceleration of the pulse-rate; six were fatal, two recovered.

Belonging partly to one and partly to the other of the two preceding classes, there were reported ten cases of papillomatous cysts. Six recovered, four were unsuccessful.

Dolan says of these tumors, "They are very intolerant of surgical interference, and are very formidable both for operator and patient." Many of them starting from the parovarium grow between the folds of the broad ligament stretching it over the cyst surface, while others, taking their origin from the nilum of the ovary, often become intraligamentous as their development progresses. These tumors are very bountifully supplied with blood, forming extensive adhesions from their inception, often impossible of removal except by enucleation, growing very closely upon the uterus, even when operated upon very early, make the case a difficult one and sometime necessarily fatal.

Yet, of every variety of ovarian cystoma, this most emphatically demands the earliest possible removal, because of its tendency to degenerative change and rupture, and, because, if it be not malignant from its commencement, it soon acquires that character. An examination of the detailed reports of the six hundred cases, shows several that were essentially fatal from various causes other than extensive adhesions or degenerative changes, yet from causes inherent in the patient and not dependent upon the operator.

Therefore if my deductions are substantially correct, we have in the whole list under consideration, rather more than sixty cases that were essentially fatal. Thirty-seven on account of pelvic adhesions, twenty-five by reason of degenerative changes, and the few additional ones just mentioned.

The statistics of these six hundred ovariotomies, made by thirty-three different operators, reported with sufficient detail to indicate the conditions attaching to individual cases, show an unavoidable fatality in at least one-tenth the whole number. And I have no doubt, that were it possible to obtain an exact history of every other ovarian case and ovariotomy in this country for the past six years, we would find this ratio of essential fatality fully maintained, and, furthermore, could we estimate accurately, those most important factors in determining the result of an ovariotomy, the patient's vitality, power of endurance and of resistance, in relation to the necessary length or severity of the operation, it is probable that we would find our proportion of essentially fatal cases still further increased: and the fatalities for which the surgeon is responsible, in like measure diminished. The American ovariotomist, therefore, operating upon all the cases presented to him — as it is his duty to do with rare exceptions — who has saved ninety per cent. of his patients, is to be congratulated, as having eliminated, practically, all deaths from any lack of skill on his part or from accidental causes.

This proportion, of course, would only hold with large numbers of cases. Those essentially fatal would be too unevenly distributed to make any small number of ovarian operations any criterion of their relative frequency.

In a general way, the deaths after ovariotomy may be divided into two classes:—

(1) Those due to lack of skill or care on the part of the operator, faulty modes of operation, or to accidents.

(2) Those necessarily fatal by reason of the existing conditions of tumor or patient or both.

Looking to the future results of ovariotomy in America, the question of how much it is possible to diminish the fatal statistics of the first class, comes to us. Certainly in the whole range of surgery, there are no operative procedures that require more special preparation and experience than ovariotomy and its kindred operations. Could all patients with ovarian cystomata be in the care of specialists in abdominal surgery, the number of deaths from lack of skill and experience in the operator would be largely decreased, and those from accidents as well, for the latter are avoided by the skill and especially by the experience of the surgeon. In the details of the operation, through its different stages, the modes of procedure are almost universally agreed upon; the only diversity of opinion and practice being in regard to Listerism and the frequency of the use of the drainage-tube.

In short, that degree of perfection has already been attained that would seem to admit of very little future improvement. Whatever advance is made, therefore, in this class, will come mainly from the increasing experience of those who perform the operation.

From this, it follows that if any great improvement in the statistics of American ovariotomy is to take place, it must be by a diminution of those deaths comprised in the second class, namely, those essentially fatal. Fortunately, too, this class contains the larger number of unsuccessful results, and also is the one in which the greatest improvement is possible.

In the twenty-five cases with degenerative changes and the thirty-seven with pelvic adhesions, the element of essential fatality was, for the most part, an acquired one, and had the operation been performed sufficiently early, in the place of this appalling list of fatalities, would have been substituted, less a few cases, a like number of successes.

The list of essentially fatal cases will be nearly obliterated from our statistics, when American physicians shall all agree in regarding a patient with an ovarian cystoma as constantly menaced with great and increasing danger to her life, and shall concur in urging its removal with the least possible delay.

Then will the statistics of American ovariotomy express in full measure the real skill and ability of American ovariotomists.

REPORT ON PROGRESS IN THORACIC DISEASE.

BY FREDERICK C. SHATTUCK, M.D.

HÆMOPTYSIS AND APEX PNEUMONIA.[1]

After briefly relating the histories of five cases Dr. Hood goes on to say: "My desire in this paper is to emphasize the fact that in certain pneumonic conditions a sharp hæmorrhage at the initial stage is symptomatic of the attack, and is, as I believe, directly caused by the inflammatory hyperæmia. In such cases, where a severe hæmorrhage ushers in the attack, we shall find the inflammatory focus very frequently at one or the other apex, and the physical symptoms of such a pneumonia are often more easily demonstrated at the posterior than at the anterior

[1] Lancet, 1886, I, p. 1157.

region of the chest. Such pneumonia, complicated with severe hæmorrhage, is peculiarly connected with lung tissue already the seat of chronic change, whether such change be due to deposition of tubercle or to chronic inflammatory changes." . . . "In the cases of apex pneumonia I have referred to the progress was rapid as compared with an ordinary lobar pneumonia; the patients were not so severely ill. May not the severity of the attack have been mitigated by the local blood-let?"

THE PATHOLOGY OF ACUTE PNEUMONIA.[2]

Dr. Shore brings out very clearly in an interesting paper the wide clinical difference between two classes of cases of acute pneumonia, and thinks that this clinical bespeaks a pathological distinction. Typical pneumonia is of sudden onset, is ushered in by a chill, and terminates by crisis; the fever corresponding in no way to the changes in the lung. The consolidation may persist for some days after the fall of temperature, may first appear after the fall, or may be very ill defined during the whole course of the illness. The author, indeed, speaks of cases coming under his observation, at a time when pneumonia was very prevalent and the hospital wards contained many genuine cases, in which the clinical course was precisely similar to that of pneumonia except that local signs in the lungs were quite absent. These he is disposed to regard as abortive cases of pneumonia, and he queries whether cases of febricula are not sometimes to be classed under this head. The apparent independence between the rational and the physical signs has been used by many writers as an argument in favor of the general and specific nature of pneumonia. That the lung affection is only a local manifestation of a general disease is believed by Dr. Shore to be true as regards the class of cases thus far considered. But the other class, that in which the changes in the lungs and the constitutional disturbance, notably the fever, show close correspondence; the temperature increasing with the local process and, in like manner, gradually subsiding — termination by lesion — is to be regarded as a local inflammation of the lung attended by general disturbance which is purely symptomatic.

Anatomically no distinction can be drawn between pneumonia as a general and pneumonia as a local disease, at least in the present state of our knowledge. It is to be hoped that a careful study of the microbes attending these processes will be made. Dr. Shore, by the way, seems to have overlooked the fact that Friedländer himself has thrown over the capsule of the ovoid pneumonia micrococcus.

How much truth there is in this theory time will show. At present it rests on a purely cliuical basis. The facts of observation and their presentment in the paper are interesting and clear.

PNEUMONIA FOLLOWED BY ABSCESS OF THE LUNG, TREATED BY TAPPING AND DRAINAGE: DEATH.[3]

A laborer, of thirty-six, who three months previously had gone through an attack of left pneumonia, from which recovery was only partial, was admitted suffering from weakness, cough, and fetid expectoration. A large cavity with liquid contents was found at the left base, the rest of the lungs being clear, and a week after entrance a large trocar was plunged into the cavity through the seventh interspace in the back; air and a few drams of stinking pus escaped. A tube was then inserted through the trocar, a carbolic solution was injected, and a large amount of pus was expectorated but nothing came through the tube. During the following days injections were frequently made into the cavity and small quantities returned through the tube; but by far the greater part of the injected fluid, as well as by the secretion, found their exit by the mouth. After a week the patient died, apparently from exhaustion. He thought that the injections promoted his comfort.

Autopsy. "On opening the thorax, both lungs filled their respective cavities. The right lung was adherent throughout to the chest-wall. The upper lobe of the left lung was free from adhesion. The lower lobe was adherent throughout, and so firmly that the lung was torn in removal. A cavity the size of a breakfast cup occupied the whole of the base of the left lung; the wall was smooth, and the cavity contained no pus; the surrounding lung tissue being almost black and solid. A bronchus of the second dimension communicated by two openings with the cavity. The drainage tube had passed into the cavity at a spot rather below its centre. The right lung was engorged and œdematous, and on incising its base pus could be pressed out, showing the passage of this fluid from one lung to the other. Heart normal."

[This case has been abstracted here, not because operative interference with abscess within the thorax is new, but because the manner of interference was wrong in the opinion of the reporter. An operation is clearly called for where there is a slight abscess of the lung, the situation of which is favorable and the pleura overlying which has become adherent. After the confirmation of the diagnosis by means of the trocar a free incision should have been made and a large double drainage tube should have been inserted. The chances of washing out the cavity through the tube would thus have been greatly increased. As it was, the trocar took the place of the second drainage tube, and some of the contents of the cavity evidently found its way into the sound lung during the forced inspiration which accompanied the violent paroxysms of coughing which are specially mentioned in the report of the case. An abscess within the lung with decomposing contents and free communication with the trachea is less favorable for operation than an empyema; but, if its situation permits surgical interference it should be treated as nearly as possible in the same way. Herein lies the main instruction to be derived from the case. The termination might have been the same but the chances of recovery would have been better. — REP.]

THE OPERATIVE TREATMENT OF BRONCHIECTATIC CAVITIES.[4]

Six cases are reported or alluded to by Dr. C. Therdon Williams and Mr. Godlee. In one the cavity was single and a brilliant cure was brought about; in the others success was only partial, largely on account of the fact that the bronchial dilatations were multiple.

The arguments in favor of the operation were:

(1) The tendency to death by septicæmia in some form, unless proper drainage was effected.

(2) The reduction in the amount of the expectora-

[2] Practitioner, May, 1886, p. 321.
[3] Brookhouse. Lancet, 1886, I, p. 111.
[4] British Medical Journal, 1886, I, p. 500.

tion, this being due not only to the removal of the matter, but to the disappearance of the effects of its irritation on the healthy bronchi.

(3) The invulnerability of the lung tissue; it being proved that punctures of this tissue gave rise to little or no disturbance of the part, or to the system generally.

The difficulties of the operation were principally those of diagnosis of the exact position of the bronchiectases:

(1) From the presence of emphysema.

(2) From the reverberatory character of their auscultation sounds which rendered exact localization very difficult.

Paracentecis of bronchiectases seemed to be indicated under the following circumstances.

(1) In cases when antiseptic treatment of all kinds having failed to correct the flow of expectoration, and to allay the harrassing nature of the cough, death by septic pneumonia seemed imminent.

(2) Where the evidence went to prove that the bronchiectases were confined to one lung, were situated in the lower lobe, and had overlying them an adherent pleura. It was not indicated where multiple bronchiectases existed in both lungs, where they were surrounded by emphysema, and where the pleura was nonadherent.

INCISION OF THE LUNG.

Truc[5] collects and analyzes most of the recent cases, the three just noticed are not included.

(1) For acute and subacute abscess of the lung the operation has been done in nine cases with seven recoveries.

(2) For bronchiectasis in ten cases with only two recoveries: it should be noted, however, that most of the fatal cases were in a desperate condition at the time of operation.

(3) In three of the twelve or thirteen cases of tuberculosis more or less improvement followed; but the cases in which an operation can be curative are very few.

(4) Thirteen cases of circumscribed gangrene are collected. In seven cases the cure has been nearly complete; in one marked improvement resulted; in some of the other five cases which proved fatal, temporary improvement was traceable to the operation.

(5) Three cases of hydatid cyst were cured.

(6) Only one case of incision for a foreign body is treated. A tooth fell into the right lung, and caused cavity formation; an incision was made, but repeated attempts to discover the tooth in the pulmonary tissue were unsuccessful. The patient was discharged in better condition.

[The above facts show clearly that there is a future for the operation, at the same time that they indicate its limitations.— Rep.]

VESICULAR RESPIRATION; HOW IT IS PRODUCED.[6]

Dr. Coats has carefully studied the respiratory sounds in a patient whose larynx had been extirpated and who breathed through a vulcanite tube of practically the same diameter as the trachea. It is sufficient here to state that he furnishes conclusive proof that the vesicular murmur is produced in the extreme distal part of the respiratory apparatus. The author's results were submitted to a special committee of the Glasgow Pathological and Clinical Society, one of the members of which committee was Dr. Gairdner, and received unanimous endorsement.

BRONCHIAL RESPIRATION; HOW IT IS PRODUCED.

Dehio[7] after careful experiments with an artificial respiratory apparatus reached conclusions which were essentially the same as those first put forth by Skoda, as to the mechanism of the sounds heard in bronchial respiration. The reporter regrets that lack of space prevents anything more than this mere statement of the fact here.

THE POSITION OF THE FLUID IN PLEURITIC EFFUSION.[8]

Our readers will have no difficulty in recalling the experiments of Garland with reference to this point, some years ago, explaining and enforcing the clinical fact first pointed out by the late Dr. Ellis that in moderate pleuritic effusion the line of dulness is not horizontal. It occurred to Dr. Symington that these experiments were open to two sources of error; the cocoa butter is of a different specific gravity from that of serum, and when injected into the pleura, excite its effects much more rapidly than does an effusion.

Symington succeeded in obtaining the bodies of several children the subjects of effusion, froze them in the horizontal position, and then made sections, sagittal and horizontal. The results support the views of Garland that the lung at first moulds the fluid, the lung being reduced in size but not altered in shape. The fluid enveloped the lung at its posterior, lateral, and superior portions; but did not separate the lower portion from the diaphragm. Symington thinks that this fluid must be pretty large in amount before occupying this supplemental pleural space; but sections must be made of bodies frozen in the vertical or sitting posture before this point can be considered as finally settled.

SHOULDER-JOINT FRICTION AND INCIPIENT PHTHISIS.[9]

Dr. Angel Money calls attention to a sound produced in the shoulder-joint during respiration, which may be heard over the apex of the lung and closely simulate the pleural friction or dry crumple so suggestive of commencing phthisis when heard in this region. The shoulder-joint friction is loudest in the joint itself, and is more readily conducted along the bones than along the muscles. Dr. Gowen first spoke of this sign which has an especial bearing on examination for life insurance.

THE CURABILITY OF PULMONARY PHTHISIS.[10]

Dr. Dettweiler is at the head of an establishment in Falkenstein, in the Tannus Mountains, where, in the course of six years, 1,022 phthisical patients came under treatment; cases which did not remain for at least a month are not included in the above number. Of these, 132 were discharged "cured," 110 "arrested." Of the 132, Dettweiler chose 99, of whom he believed he could obtain trustworthy information, and in all these cases, save one, he received replies either from the patients themselves or from their physicians. During three to nine years 11 had died; 12 had had a

relapse, but were considered well again at the time of the report; in three the disease was active; the other 72 patients had remained quite well for periods varying between three and nine years, and were pursuing their avocations. More than half of the latter class were under thirty years of age when they first came under treatment. It should be stated that the patients belonged to the well-to-do class. The treatment was simply hygienic in the widest sense. The author expresses the hope it will, in the future, be possible to cure more than half the cases by early and judicious treatment.

[Even at the risk of being tedious, it is proposed to continue to call attention to such careful and conscientious studies as the above seems to be. The more the opinion gains ground among physicians and the public that phthisis is often curable, the more curable it is likely to prove.—REP.]

THE CONTAGIOUSNESS OF PHTHISIS.[11]

A woman whose father, two paternal uncles and an aunt, brother and three sisters, died of phthisis, and who was herself the subject of dyspnœa and hæmoptysis, married, between the years 1872 and 1883, three healthy men of sound parentage. The first marriage was contracted in 1872, and the husband died of phthisis in 1879; the second husband, married in 1879, met a like fate in 1881; the third, married in 1881, was in the last stages of phthisis in 1883, in which year the woman herself succumbed to the disease.

[This series is somewhat remarkable in that the husbands were the victims; the transmission from husband to wife is much more common than is that from wife to husband. Weber relates the case of a husband who infected four healthy wives in succession, outliving them all.—REP.]

ASPIRATION OF THE RIGHT AURICLE: DEATH.[12]

The patient was admitted into the hospital in the last stages of cardiac failure consecutive to mitral disease; dropsy, cyanosis, stupor, and dyspnœa being the prominent symptoms. Stimulants and digitalis proving ineffectual, the next day Dr. Westbrook inserted a small, hollow needle into the right auricle through the third right intercostal space, at the sternal border, and drew off eighteen ounces of blood. "During the operation the radial pulse improved somewhat, and this improvement continued for half an hour. Toward the close of the operation the patient regained consciousness. The respiration improved somewhat, and the color somewhat improved. But, after an hour, he sank again, and died seven hours after the operation." At the autopsy, besides the usual lesions belonging to mitral stenosis with failure of the right ventricle, a considerable amount of blood was found in the pericardium, and "the orifice made by the puncture was still visible, and pressure upon the heart, while, *in situ*, caused a little oozing; the auricular wall was very much attenuated from long over-distension." In other words, the immediate cause of death was clearly hæmorrhage into the pericardium through the puncture.

[Our readers may remember that this operation has been practised by Dr. Westbrook several times of late years, and has been strongly advocated by him and by Dr. Leuf, of Brooklyn, in the medical journals. It is to be hoped that the unnatural operation may now be allowed to die a natural death. In such cases as that reported, the abstraction of blood from the veins is clearly indicated, and often yields astonishing results; drugs given by the stomach are not absorbed, or fail to act. But the blood should be withdrawn either by venesection or by the application of a dozen leeches over the liver — methods which attain the same end by unloading the distended right ventricle, and in themselves involve no danger to the patient, even if, as must sometimes be the case, he is too far gone for relief. Dr. Westbrook is to be thanked for reporting his bad cases, as well as his good.—REP.]

CONGENITAL STENOSIS OF THE DESCENDING AORTA.[13]

M. Barié, having met with two cases of this condition, has been at the pains of collecting the cases reported during the last hundred years, a total of ninety-one. The paper is very full, and of the twenty-three conclusions in which it is summed up, we select those of most practical importance:

(2) The localization is constant, the stenosis occupying the region between the ascending and descending aorta, which corresponds to the "isthmus of the aorta" of fœtal life, and reaching its maximum a little below the point where the left subclavian is given off, at or near the entrance of the ductus arteriosus.

(3) The stenosis is generally single; when it is double, the interposed segment of the aorta is almost always dilated.

(8) The dimensions of the stenosis are variable: the average length is about 0,020 millimeters; the calibre varies from that of the little finger to that of a hog's bristle.

(9) The wall of the aorta is sometimes normal in other respects at the contracted point, but in more than a third of the cases atheromatous changes were found, and, exceptionally, the coats were thinned.

(10) In more than half the cases, the aortic segment between the heart and the stenosis was dilated, and death has not infrequently resulted from rupture of the aneurismal enlargement. The distant portion of the aorta may also be dilated.

(12) The ductus arteriosus is nearly always obliterated, but was more or less patent in eight cases.

(13) The condition brings in its train changes in the heart, and also in the great arteries.

(a) The cavities of the heart are dilated, and the left ventricle is often hypertrophied, changes which may be intensified by secondary valvular lesions.

(b) In consequence of the dilatation of the large arteries given off from the aorta, the circulation in the heart and upper extremities is maintained, or may be unusually active; while in the thorax, abdomen, and lower extremities it is strikingly modified, being carried on principally by branches from the subclavian.

(14) In thirty-eight per cent. of the cases there was also some other congenital malformation, such as abnormal communication between the cavities of the heart, hair-lip, cleft palate, etc.

(16) As regard symptoms the cases may be divided into three groups:

(*a*) In numerous cases the lesion was not recognized during life and was found accidentally at the autopsy.

(*b*) In other cases patients consulting a physician for some ailment were recognized as the subjects of stenosis of the aorta although this condition had not of itself resulted in any impairment of health.

[11] Lasetsky, Revue des Sciences Médicales, 1886, I, p. 832.
[12] New York Medical Journal, 1886, I, p. 447.
[13] Revue de Médecine, 1886, p. 343.

(c) The third and largest class included those who suffered from the symptoms of chronic heart disease.

(21) The prognosis is relatively favorable, many of the patients dying in advanced years. The average age of all the cases was thirty-four years.

(22) In diagnosis, mediastinal tumor, aortic aneurisms, and all causes of intra-thoracic pressure must be excluded.

(23) The affection depended on an arrest of development of the isthmus of the aorta, which seems to be the result of premature closure of the ductus arteriosus; traction is thus exerted on the isthmus of the aorta and its physiological growth is impeded.

No satisfactory explanation can at present be given for the rare cases in which stenosis of the aorta and patency of the ductus arteriosus, are co-existent.

ENDOCARDITIS OF THE RIGHT HEART.[14]

Dr. Byrom Bramwell subjected to a careful analysis all the cases of valvular disease which came to the post-mortem table during the three years that he was pathologist to the Edinburgh Royal Infirmary. The number of cases presenting marked eye evidence of valvular disease was one hundred and thirty-one, and of these eighty-three were classed as simple endocarditis; the tricuspid valve was affected in twenty-nine per cent. of these, and in most of them the lesions were of more or less recent origin.

The following are the most important practical conclusions to which the investigation has led the author:

(1) Pathological experience shows that right-sided endocarditis is much more common than is usually supposed, and this conclusion is in no way contradicted, but on the contrary rather confirmed, by clinical evidence and clinical facts.

(2) That a tricuspid murmur occurring in the early stages of acute rheumatism in a previously healthy person who is not anæmic, is indicative of a rheumatic affection of the right heart.

(3) That although right-sided endocarditis is of frequent occurrence, it is comparatively seldom followed by permanent organic disease of the tricuspid valve; in short that right-sided endocarditis is an eminently curable affection.

If these conclusions are correct and tricuspid is less liable to be followed by permanent damage than mitral endocarditis, do we not receive from Nature an important therapeutic hint? What reason can be assigned for the relative immunity of the tricuspid other than the relatively slight strain to which it is subjected? A new illustration of the importance of rest in the treatment of acute valvular disease is thus afforded.

— The *Boston Advertiser* says: "A physician of large experience remarked the other day that when he began the practice of medicine he was worried because people put so little confidence in him, and now he was troubled because they trusted his judgment so implicitly. He seemed to think that to be thought infallible was far more burdensome than to have one's fallibility emphasized as in his younger days."

— Irish Tramp. — "Is this a lying-in-hospital, mister?" Janitor.—"Yes, this is a lying-in-hospital." Tramp. — "Then I guess it's the right place for me, for I've been lying out these three nights."

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION OF OBSTETRICS AND GYNÆCOLOGY.

ROBERT B. DIXON, M.D., SECRETARY.

May 19, 1886, Dr. James R. Chadwick in the Chair.

Dr. J. R. Chadwick reported

A CASE OF EXTRA-UTERINE FŒTATION, WITH PRESENTATION OF THE SPECIMEN.

Dr. John Homans showed a very beautiful specimen, the result of an abdominal pregnancy of seven years' duration. The bones of the skeleton, almost wholly complete, had been mounted by Dr. O. K. Newell. The case is described at length in the *Boston Medical and Surgical Journal*, May 20, 1886, Vol. CXIV, No. 20.

Dr. O. W. Doe mentioned a case that he reported two years ago. It was that of a colored woman who came to the City Hospital to be treated for diarrhœa. Upon examination, a mass of bone was found projecting into the rectum. Ether was given, and the mass, which had sloughed, came away easily. The only bones in it were those of the skull. The woman's statement was that she was last pregnant eight years before.

Dr. E. G. West, whose case was the one operated upon by Dr. Homans, said that the peculiarity of the case was the two cysts beside the fœtal sac. It was a question with him whether the fœtal remains might not have been the contents of a dermoid cyst.

Dr. Fitz remarked that in the dermoid or congenital cysts one does not find such large bones as in this case, so probably these bones were the result of pregnancy.

Dr. J. C. Irish, of Lowell, read a paper entitled

DISCUSSION OF STATISTICS OF OVARIOTOMY.[1]

Dr. John Homans thought that the ratio of recoveries and deaths depended largely on the operator. For himself, he had had, out of cases entirely unselected, thirty-eight successive recoveries and sixty-seven cases, with four deaths, but this is a better average than that of the whole two hundred and fifty ovariotomies that he has done, in which the recoveries are very nearly ninety per cent. Now, by selection, this percentage may be improved. If an operator has an assistant to whom he can turn over the doubtful cases, of course he will be able to make a better showing. Dr. Homans feels that in most of his fatal cases the result is to be attributed to some omission or commission on his part — some slip up; or being a little tired, or a little hurried, and he feels this not in a morbid way at all, but only as making him take more pains and precautions with every succeeding case. Some of the deaths after ovariotomy are unexpected and unexplainable. When a simple operation is followed by death, and the autopsy shows no adequate cause, we say the woman died from "septicæmia," and so she did, but all we know is that she died in consequence of ovariotomy. If a man has a hundred recoveries in succession, it would seem as if he must have had a remarkable series of cases if they were *entirely* unselected. Experience and surgical resource goes a long way in obtaining good results. As a general rule, the earlier

[1] See page 153 of this number of the Journal.

the operation, the better the result, but there may be such a thing as too early an operation. It will not do to wait in most cases of papilloma, but you cannot tell that the tumor is papillomatous until you remove it. There is no operation in surgery where experience is of more advantage than in ovariotomy, and one might say the same of abdominal surgery generally.

Dr. Lyman thought that there are certain cases that are essentially fatal, and that Dr. Homans was wrong in taking any blame to himself for a certain portion of his deaths.

Dr. Kimball, in speaking of the uncertainty regarding the results of ovarian operation, remarked that now and then cases, apparently the most promising for recovery, turn out badly. By way of illustration, he said that when last in London he called on Spencer Wells, and was shown a letter the latter had just received from Keith, of Edinburgh. Wells had seen Keith remove an ovarian tumor only a few days before. The case was, in every respect, as favorable for a successful result as could be desired. To the great surprise and disappointment of both gentlemen, this patient died in three days after the operation, but from what cause no one could tell. Then again, one sometimes has to deal with a case where the conditions are such as to contra-indicate an operation. Not long since, a patient was sent to Dr. Kimball from Canada, with a view to the removal of an ovarian tumor. Upon examining her case, he found difficulty in making a satisfactory diagnosis. The history of the case, as given by a highly-intelligent physician, taken in connection with the present feeble condition of the patient, led to the suspicion that the tumor in question might be malignant. He was, therefore, in doubt as to the expediency of interfering with it. Patient and friends, however, chose to take the risk, and he operated. On opening the abdomen, he found no ovarian tumor, but instead, a marked case of papillomatous cancer of the uterus, and so far advanced in the process of degeneration as to forbid any attempt to remove it. Contrary to expectation, the patient recovered from the operation, and in less than a month returned to her home in Canada, greatly relieved. He afterwards received a note from her, expressing her thanks for the great benefit she had received from the operation, saying also, that she was hopeful of still further improvement. Of course this case must ultimately prove fatal.

He mentioned another case of a patient he was called to see in Providence several years ago. She was suffering from an ovarian tumor, which, from its history, he thought might be malignant. He advised her to return to her home in Nova Scotia before she became too feeble to get there. She was greatly disappointed at his refusal to operate, and made him promise that if she improved in health, he would go to her home and operate whenever she saw fit to send for him. She held him to his promise, and three months later he went to Nova Scotia and removed from his patient a small-sized ovarian tumor, which proved to be of a decidedly malignant character. She recovered from the operation, and for a time seemed in a fair way of complete recovery, but he has since learned that she lived scarcely a year from the date of the operation.

Dr. J. W. Elliot had operated fifteen times with one death.

He thought that the technique of the operation was well settled and could easily be learned, but the important things in keeping the mortality low were cleanliness and good judgment. He did not believe it was possible for an operator to choose his cases so as to make a good record; for, the cases that seemed the most favorable often turn out the most difficult and *vice versa*. The only fatal case he had had seemed an easy one before the operation, and yet it turned out a very complicated double ovariotomy, one cyst being papillomatous and the other having a twisted pedicle. On the other hand, he had operated with a good result on a large suppurating cyst with a temperature of 103.° and a pulse of 120, where there was little hope of recovery. In this last case it became necessary to stitch the cyst to the abdominal wall and put in a drainage tube.

Dr. Elliot was decidedly in favor of early operations; the removal of a small simple cyst was attended with very little danger, but every day the cyst remains and grows it is liable to undergo changes which more than double the dangers of the operation; for instance, it may become malignant, the pedicle may become twisted, it may become inflamed and suppurate, it may rupture and cause peritonitis, it may become complicated with pregnancy, nephritis, thrombosis, or some accidental disease. Dermoid cysts are especially liable to become adherent or suppurate. Every ovarian tumor must some day come to operation. All things considered, Dr. Elliot thought it was best to operate as soon as the tumor is discovered.

Dr. Lyman said that statistics were now of comparatively little importance. Thirty years ago very few ovariotomies had been done and it was thought by many of the most distinguished surgeons that the operation should be condemned. But others thought it had a future before it, that it required more careful investigation, beginning with unbiassed statistical inquiry. After a year's careful research he published the statistics alluded to by the chairman. Only about 300 cases which could be *fairly authenticated* could be found in American or foreign literature. These, together, gave a mortality of only forty-two per cent., notwithstanding the inexperience of that day in abdominal surgery; not more than many operations which were considered to be perfectly legitimate, comparing favorably with such as strangulated hernia or amputation of the thigh. These results awakened a new interest and under the stimulus given by Spencer Wells and others, the cases in this country and England alone are now numbered by thousands, the mortality with some operators being not far from ten per cent., and the technique has become so nearly perfect that it seems as though any further improvement must be sought for in improved methods of diagnosis.

Dr. Farlow said that the statistics of ovariotomy would be more favorable if one fact were more commonly borne in mind, especially by general practitioners: that is, the harmfulness, in most cases, of tapping and the effect that it has on the formation of adhesions. This is, of course, well known to ovariotomists and gynæcologists, but among those who seldom see an ovarian tumor the idea seems to prevail that, because tapping is useful in ascites, all collections of fluid in the abdomen can be treated in the same way and with like benefit. If, on the contrary, it could be impressed on the general practitioner, that if there is a chance of the tumor's being ovarian, it should not be tapped but let alone and sent early to an ovariotomist for examination and advice, we should find the num-

ber of deaths after operation due to extensive adhesions much less than at present.

Dr. Reynolds referred to the duty of the general practitioner in cases of ovarian tumor. He considered it a serious matter for a general practitioner to say to a woman, you have an ovarian tumor and ought to be operated upon within four weeks. You have one chance in ten of dying. The patient is in a good condition, what shall she be told? How sure is it that delay is unwise when the tumor is evident?

Dr. Homans answered, that if a tumor had been growing slowly, and was increasing in size slowly, that one need not hurry in operating; one need not hurry in removing a parovarian cyst, that is, one of the broad ligament, but symptoms of a twisted pedicle, or rapid growth of a tumor, or distress, or rapid constitutional disturbances, ought to lead to *immediate* operation. Dyspeptic symptoms, diminution in the amount of urine, œdema or ascites require prompt but not immediate (that is, within a few hours) removal of the cyst, so also would any obstruction to the circulation from pressure. In regard to adhesions it is impossible to make an accurate diagnosis; posterior adhesions are rare, and these are the ones most to be dreaded. Again, if a woman is perfectly comfortable and has very young children to care for and is near her surgeon, she might wait, while a person who was going to a distance not to return for years could not.

Dr. Homans further said, given a case of ovarian tumor that is malignant with contents looking like vaseline, what is one going to do? The cyst cannot be tapped for the fluid will not flow. Should the woman be permitted to die as she is, or should the chances of an operation be taken to give her a few months' respite when the disease will recur and she will die? He does not see how one can tell what parts are invaded. He operated the other day on a double ovarian tumor and found malignant disease, which will recur. Another case was one of papilloma. The patient had been tapped thirteen times in eleven years, and the tumors were supposed to be fibroids, immovable and irremovable, and this verdict had been given in one of the largest cities; but at last he decided to operate. The tumors were papillomatous, and in operating the bladder was cut into requiring ten stitches. The woman has gained forty pounds in weight and is now well.

Dr. Reynolds asked if much importance was given to adhesions by ovariotomists.

Dr. Irish replied that, while the omental and parietal adhesions existing in a moderate degree did not greatly increase the dangers of ovariotomy, yet extensive visceral and especially pelvic adhesions had seemed to add very much to the risks of the operation. Among the 600 cases mentioned in his paper, were found seventy-five with extensive pelvic, or with pelvic and visceral adhesions. Of this number forty-two died. Hence, in this list, adhesions of the latter character had been followed by great fatality — greater than had attended the removal of degenerate cysts.

TUBO-OVARIAN CYST. HÆMORRHAGE INTO THE TUBE. OPERATION.

Dr. Elliot showed a tubo-ovarian cyst which he had removed by laparotomy on account of hæmorrhage into the tube.

The Fallopian tube was dilated, tortuous and elongated to the extent of nearly six inches. Its wall was in general at least one-eighth part of an inch thick and in places nearly twice as thick. The outer end was connected with a sacculated cyst as large as two fists. The cavity of the cyst and the canal of the tube communicated by an opening one-eighth of an inch in diameter. The cyst represented the ovary and was inflamed and injected. There was also a cyst of the broad ligament which was as large as two fists. There was then a chronic salpingitis, a tubo-ovarian cyst, acutely inflamed and a parovarian cyst, all in one specimen. Dr. Elliot had been called to see the patient by Dr. Worcester, of Waltham, on account of pelvic inflammation and hæmorrhage from the vagina. He had found a tumor in the pelvis reaching two inches above the pubes. Twenty-four hours later the tumor was as high as the umbilicus. The temperature was 101¼°. He thought it must either be an abscess or hæmorrhage into the tube, but in all probability the latter, and accordingly opened the abdomen. The tube and cyst were found greatly distended with blood and pus. The operation was exceedingly difficult. The patient recovered promptly.

AMERICAN OPHTHALMOLOGICAL SOCIETY.[1]

Dr. Mittendorf also described a case of

MELANO-SARCOMA OF THE CONJUNCTIVA AND CORNEA.

Mrs. M., aged forty-six, came under observation August 23, 1884. In April of that year, a black spot appeared upon the lower part of the conjunctiva and was removed. When she again came under observation two other tumors had appeared. They were about the size and shape of cucumber seeds. Two or three spots looking as though ink had been dropped on the eye-ball were also noted. The tumors were movable and the conjunctiva surrounding them slightly congested. Otherwise, the eye-ball was normal and vision almost perfect. The growths did not affect the left eye which was highly astigmatic. The patient was a strong, hearty woman with no appearances of cachexia. There had been no injury to the eye and the family history was good. The pre-aural glands and those of the neck were not enlarged. The tumors were removed and the wound in the conjunctiva brought together with sutures. Healing took place rapidly.

Four months later she returned with two growths starting from the lower portion and the outer canthus of the same eye. There was also a small flat growth on the cornea, not connected with the tumors. The tumors were again removed and the patient returned to her home.

In the spring of 1886, she again made her appearance with the eye closed. There was a small tumor the size of a cherry which had developed at the seat of the former growth. The tumor with a portion of the conjunctiva was removed. A pre-aural gland and some glands in the neck were found slightly enlarged. The general health remained good. She had, in fact, gained in weight since the previous operation.

Four or five weeks ago, she again returned with another growth. The eyelids could not be separated. An incision was made and the tumor removed.

Microscopical examination showed the growth to be a sarcoma with round cells. The melanotic appear-

[1] Concluded from page 140.

ance was chiefly due to hæmorrhage in the parenchyma. Pigment granules were also present.

DISCUSSION.

DR. H. D. NOYES, of New York. In a case of melanotic sarcoma on which I operated some years ago, the disease has not returned.

DR. H. KNAPP, of New York. I have seen a number of these cases on which I operated as carefully as possible, but they have all after a variable period, relapsed.

DR. O. F. WADSWORTH, of Boston. I know of two cases of episcleral epithelioma which did not recur for several years after removal.

THE USE OF HOT WATER IN SOME OF THE CORNEAL AND CONJUNCTIVAL INFLAMMATIONS,

by DR. B. E. FRYER, of Kansas City.

In this plan of treatment, the water is used at as high a temperature as can be borne. After a few hours a temperature of 140° can be borne. The water should not be of a lower temperature than this and as much higher as the patient can stand. A method of using it is by fomentation with a napkin dipped into the hot water, not wrung out, and applied to the closed eyelids. This is continued for half an hour at a time and repeated every one, two or three hours day and night. It may also be applied by suspending a vessel above the patient and allowing the water to escape through a tube, thus keeping up a continuous action of the hot water. In some cases the temperature may be raised almost to the boiling point. During the intervals between the applications a cloth wrung out of hot water is allowed to remain over the eyes. In some cases of purulent ophthalmia, the hot water may be thrown into the conjunctival sac.

In purulent conjunctivitis this application cuts short the attack more quickly and safely than the use of ice-cold water. In gonorrhœal ophthalmia, it quickly lessens the swelling and diminishes the occurrence of ulceration of the cornea. If ulceration has commenced, it is less likely to progress and the amount of cicatricial tissue is lessened. In these cases, I occasionally use instillations of sublimate solution of finely powdered iodoform. This plan of treatment is not so readily applied in ophthalmia neonatorum. In catarrhal conjunctivitis and phlyctænular ophthalmia, it is a good adjuvant. In acute and chronic keratitis it is useful. Its most marked effects are seen in corneal ulcer. The small amount of opaque tissue left is astonishing. The pain and photophobia are also diminished by the hot water.

DR. WILLIAM F. NORRIS, of Philadelphia. I have had good results from the use of hot water in gonorrhœal ophthalmia. It is a comfortable application and several apparently unfavorable cases have gotten well under its use.

DR. SAMUEL THEOBALD, of Baltimore. I have not used hot water in purulent troubles, but in interstitial keratitis and specific keratitis its use has been beneficial. I think that it favors absorption of the opacity of the cornea. Constitutional treatment and the use of atropia of course accompanied the applications of hot water.

ASTHENOPIA, AND THE CHANGES IN REFRACTION IN ADOLESCENT AND ADULT EYES,

by WILLIAM F. NORRIS, M.D., of Philadelphia.

The speaker first referred to the changes occurring in the shape of the eyeball at various periods of life. It is regarded by some as not necessary to correct slight errors of refraction, but the author considered their correction as of great importance when they produce asthenopia. By removing the trouble the congestion and softening of the eye is removed and the lengthening of its visual axis is prevented. This congestion and softening were regarded as important factors in the production of astigmatism and conical cornea.

A number of cases of diminishing hypermetropia and of hypermetropia passing into myopia were described. Diminishing hypermetropia and increasing myopia are simply different stages in a process essentially the same. They are both the result of softening of the eyeball and slow distension in the direction of the visual axis. Careful correction in these cases is one of the best means of preventing their further progress. The eyes should be carefully measured under the influence of a mydriatic. The enforced rest of the eye, thus obtained, is an important aid in diminishing the congestion. During the dilatation of the pupil, dark glasses should be used even in a mild light. All cases of hypermetropia where there is a decided difference in level between the disk and the macula should be carefully watched.

DISCUSSION.

DR. E. GRUENING, of New York. I have been much interested in one group of cases. The patient on arising has pain in the eyes with photophobia, passing off in an hour or two. He was not able to fix on any object for any length of time. There is also lachrymation. When I find such symptoms, I look into the nose and almost always find evidence of nasal disease. The nasal reflex plays an important part in our modern pathology. All the affections due to nasal irritation are increased by the recumbent position, for this favors congestion of the erectile tissue of the nose. It is not, probably, that eyes which have rested all night would manifest painful sensations, and this fact tends to exclude ordinary asthenopia in these cases. I have treated these patients by removing the nasal trouble, and in a series of 200 cases, 150 have been benefitted, while the remaining fifty have passed from observation.

The subject was further discussed by Drs. Theobald, Harland, Risley, and Randall.

(To be continued.)

ANNUAL MEETING OF THE AMERICAN NEUROLOGICAL ASSOCIATION.[1]

JULY 21, 22, 23, LONG BRANCH, N. J.

EXECUTIVE session was then called, and officers for the ensuing year elected as follows: *President*, Landon Carter Gray, Brooklyn, N. Y.; *Vice-President*, J. Van Bibber, Baltimore; *Secretary and Treasurer*, G. M. Hammond, New York; *Councillors*, B. Sachs, New York, Wharton Sinkler, Philadelphia.

A paper was read by DR. L. C. GRAY, on

LESION OF BOTH TEMPORAL LOBES, CAUSING ALMOST ABSOLUTE LOSS OF MEMORY OF EVENTS, WITHOUT WORD DEAFNESS, OR DEAFNESS.

Male, aged forty-three years, unmarried, with a

[1] Continued from page 142.

probable history of specific disease. Patient was admitted to the Hospital for Nervous and Mental Diseases, in the early part of June, remaining there until the latter part of the month, when he was removed to the Morris Plains Asylum, where he died in October. During the whole of this time careful observation failed to detect any other symptom than that of absolute loss of memory of events without word deafness or deafness.

At post-mortem there was found a lepto-meningitis of both the right and left temporal convolutions which meningitis also extended around the fissure of Sylvius, involving the gyrus marginalis, and the bases of the two ascending frontal and the ascending parietal. A number of letters of the patient were read which showed this peculiar loss of memory and his intellectual preservation in other respects.

JULY 21, AFTERNOON SESSION.

The PRESIDENT then called for discussion of Dr. Gray's paper.

DR. WILDER said that he had not quite understood the lesion Dr. Gray referred to in his paper. Dr. Gray replied that meningitis was the only lesion in the case.

DR. ZENNER, of Cincinnati, Ohio, asked to what extent the cortex was affected. Dr. Gray replied that both temporal lobes were softened and the layer of grey matter much less than any other portion of the brain. No microscopical examination was made.

Dr. Zenner asked if there was any confusion of speech. Dr. Gray answered he was told there was none at all, and he knew there was no evidence of it in his letter.

Dr. Zenner remarked he would not like to accept a case like this where softening was not detected, as refuting the ideas which have been generally accepted that the temporal convolutions were the receptacles of speech so to speak; for a meningitis does not necessarily rob the parts underneath of their function.

DR. GRAY stated that both temporal and sphenoidal convolutions were softened.

DR. ZENNER thought that could have occurred in the last few days of life. As regards the temporal convolutions being the seat of hearing he thought that had been less definitely established: that it was only one of the organs in physiology; and that there was nothing which he knew of in pathology which would establish the temporal convolutions as the seat of learning, but lesion of the temporal had been established to result in word deafness.

DR. V. P. GIBNEY, of New York, then read a paper on

PSEUDO-HYPERTROPHIC PARALYSIS,

illustrating the same with a case and presenting specimens from the spinal cord which had been secured at the post-mortem, and afterward prepared and mounted by Dr. Amidon.

The Doctor remarked that he did not propose to advance any startling or new theories, but he wished to put a case on record substantiating the appearances of those microscopic specimens presented by Dr. Amidon. Until recently he had been under the impression that the lesion of pseudo-hypertrophic paralysis was more frequently located in the spinal cord. He spoke of the lesions occurring in the spinal cord and those originating in the muscles themselves, and which of late have been the subject of much discussion.

The case, on which the paper was based, came under the author's care on April 10th, 1878, and was seen almost daily for one year, and since that time has reported occasionally; death resulting from catarrhal bronchitis on December 30, 1885. The patient was a male, eight years of age when he first came under Dr. Gibney's care; the loss of power dated from the second year of his life; no medical advice in particular was secured until he was six years of age, now some ten years ago. The father, mother and children, some four or five in number, have all some peculiarity of speech. Three children had died from tuberculous meningitis, so reported; one brother, two years younger than the subject of the history, is affected in the same manner and his case is progressing the same way.

DR. AMIDON then presented the specimens under the microscope mentioned by Dr. Gibney; he also exhibited some sections of a normal spinal cord showing the contrast between the healthy and diseased cord.

The PRESIDENT then called for the discussion upon the paper.

DR GIBNEY asked if there was any cord lesion in pseudo-hypertrophic muscular paralysis, whether the latter stages of this disease are distinctly clinical or whether they run one into the other.

DR. G. W. JACOBY, of New York, remarked, the last time he had the pleasure of demonstrating a case, and in seventeen cases recorded, there was no change in the anterior cord; but on the other hand there was in the muscular tissue a shortening of the fibres, an increase of connective tissue and an increase of fat. In some cases there was no reference made to the motor nerves in the muscles themselves.

In others where pieces of the muscular tissue had been removed and examined microscopically, atrophy of the terminal filaments of the motor nerves was found with other changes. I would ask Dr. Amidon whether he paid any attention to that.

DR. AMIDON replied that Dr. Gibney had sent him a portion of the dorsal muscles for that purpose, but he had not yet examined it.

DR. SACHS remarked that the subject of the paper was of practical interest at this time in neurology as we had had an era in which diseases of the brain were discussed mostly. Then there was an era of interest in the peripheral nerves. The doctor thought that in direct distinction to Charcot's school we must take into consideration what Ayers had done. He supposed that all knew that this condition was common in the young, but there was another form which was called juvenile muscular atrophy; juvenile atrophy would probably be classed as a motor and spinal cord affection. He thought there was one clinical point which would enable us to establish a differential diagnosis, and that would be in regard to the electrical reaction, if the affection is peripheral only, the electrical action might slightly diminish or increase, but where degenerative action has occurred the reactions are not altered.

DR. ZENNER remarked that we knew that a change in the muscular tissues produced by disease, will produce a change in the ganglionic cells. He thought that where the disease commenced in the muscles and nerves, there would be but slight change in the cord. Perhaps only in the size and no change otherwise in

the inter-cellular tissue: and it seemed as though the change there might be secondary and that the extensive disease in the periphery is primary. He thought however that where there is extensive disease in the anterior portion of the cord the disease would be primary, but that the slight change would be secondary.

Dr. Gibney remarked that it was true that peripheral lesions might cause central troubles probably travelling in along the nerve filaments, but there was no decided proof to that effect. In some cases there is a neuritis produced in animals where caustic has been used as also as in human beings where it has been used upon the scrotum or testicles. One of these cases that I have known of peripheral disease has been of a decided nature.

Dr. Massey, of Philadelphia, thought that if there was no life in the muscles the cells would be affected.

Dr. Zenner explained that he had in view at the time he spoke the idea of serious injuries, as for instance, the loss of an arm, after which atrophy had been found in the brain or cord.

Dr. Mills asked an opinion as to the difference between pseudo-hypertrophic paralysis and muscular atrophy: stating that one of the brains he exhibited in the morning was from a youth who presented these two diseases together. He was one of three brothers in all of whom these diseases were conjoined. Some portions of the muscles were removed and a published report appeared some years ago of the same by Dr. Curlin. The doctor's own convictions were that these two diseases were practically the same thing rather than original central affections.

Dr. Lloyd then stated that he had reported the case of a female in whom pseudo-hypertrophic paralysis and atrophy of the muscular tissues was combined, there was wasting of the calf muscles and also those of the forearms but there remained some faradic contractility; the loss of muscular power was so great she could hardly raise her head from the pillow. There are also marked changes in her joints, there being hardly any olecranon process left, and the patellæ being only one-third of their normal size.

Dr. Gray remarked that he had a case in his wards who had been some six or seven years in dying; he has grown enormously fat for the reason he has been kept quiet; he is helpless in his lower extremities and almost so in his upper ones, but he takes an enormous amount of food, and to look at him, one would suppose it to be a case of pseudo-hypertrophic muscular paralysis.

Dr. G. M. Hammond, of New York, remarked that the destruction which occurred in the cells should not necessarily produce destruction of the spinal cord or atrophy, but if the disease extended from the muscles up the nerves it might do so.

Dr. Amidon said that he thought they came under progressive muscular atrophy and therefore there would not be any caving-in — so to speak — of the spinal cord.

Dr. Hammond replied that a disease which commences in the spinal cord might be extensive enough to produce caving-in of the anterior horns whereas in the specimens shown the horns seemed to be in very good shape and the disease involves the cells.

Dr. Durkem, of Philadelphia, thought that point was well taken, for in some of his specimens there was absolutely no change in the contour of the horns. He considered that in this disease there was an atrophic condition of the cells more purely; there is not an active inflammation but simply a shrinkage and gradual disappearance of the cells.

Dr. Gibney in closing the discussion thought the absence of the cells and slight loss of contour sufficient to account for the great muscular changes. But upon this point he was not satisfied, as to whether the loss of function and tone would not of itself account for the disappearance of the cells and their shrinkage.

Dr. Sarah J. McNutt, of New York, read a paper upon

MULTIPLE TUMORS OF THE CEREBRUM, PROBABLY OF SPECIFIC ORIGIN, OCCURRING IN AN INFANT.

The history of the child was as follows: Female, one year of age; was a nursing baby and owing to the carelessness of the mother was frequently exposed unduly. Parents both addicted to drink but no specific history or phthisis could be discovered, they were apparently fairly healthy.

The child on being admitted to the ward had a temperature of 102½°, pulse 160, respiration 44: there was occasional twitching of the extremities, head rolling and thrown from side to side. In the lungs râles were distinct, also dulness in places with bronchial respiration. The temperature gradually rose in spite of all treatment and death occurred twelve hours after being admitted to the hospital.

The autopsy revealed in the lower lobe of the left lung a yellow caseous mass about the size of two peas, the liver also being affected in the same manner, varying from the size of a millet seed to a pea; in the spleen were found deposits of the same; the intestines being also ulcerated in several places. The brain large and soft, was much distended by dark venous blood, but no evidence of thrombosis appeared; the pia-mater was congested and in some of the fissures pus of a greenish and yellow character was discovered. Both Sylvian arteries were nodulated and apparently thickened. In the left ascending frontal convolution just beneath the surface, were two caseous nodules the size of marbles which shelled out as though encapsulated. Similar nodules were found in the parietal and occipital lobes. Under the microscope these nodules revealed an abundant cellular formation, interspersed with thickened bloodvessels and cheesy zones.

The writer of the paper thought that syphilitic lesions of the young are rarely diagnosed, and considered this to be a marked case of gummatous infiltration; concluding that in the treatment of these cases we must rely on mercury promptly exhibited, but that of all methods inunctions seemed to afford the best results, the gummata in children apparently belonging to the secondary instead of the tertiary stage.

Dr. Wilder asked what was the composition of the nodules.

Dr. McNutt replied they were vascular and filled with large round cells.

Dr. G. Belton Massey, of Philadelphia, read a paper on

THE CAUSE OF ELECTROTONUS AND THE NORMAL FORMULA OF POLAR REACTIONS,

which was discussed by Dr. Jacoby and Dr. Gray.

JULY 22. — SECOND DAY. — MORNING SESSION.

Dr. Jacoby read the

REPORT OF THE COMMITTEE ON ELECTRICAL DOSAGE.

"That special rules for the application of electricity did not exist. Individual differences between patients and diseases make this impossible."

"They advocate measures adopted at the National Medical Congress, 1886, as recognizing certain electrodes."

"Knowledge of the current strength is not sufficient to know."

Report accepted and recorded in the proceedings of the Association.

Dr. Gray believed some thought should be taken of the substance of which the electrodes were made, and also as to the coverings of them as it would make a great difference in calculations; again, with what the sponges are wetted would make a difference, the temperature of the water must be taken into consideration; his rule being to use water as hot as the patient can bear it. The question of a galvanometer should also be considered.

Dr. Mills replied there was nothing in the resolution which would disband the Committee.

Dr. Lloyd stated that he had felt a great deal of dissatisfaction in using electricity especially in electro-gynæcology, because he did not know what strength would produce certain effects; the area of surfaces making differences in the strength; the question to decide is how much current will produce catalytic action; for instance, if you want to promote absorption of an inflammatory deposit in pelvic cellulitis or in stricture of the urethra, etc.

Dr. Webber stated that as far as his experience went, an electrode, no matter of what it was composed, should be if possible square; he had discarded the use of oval ones. He thought the dosage of electricity an individual matter and that no committee could lay down laws for its administration.

Dr. Massey thought there should be a standard milliampere, but unfortunately we have not any milliamperes that are the same unless very expensive. He thought it desirable the Society should purchase a good meter for the use of instrument makers, to be left in New York City. He thought the Committee had devoted too much time to therapeutics, the points to be gained are the determination of milliamperes; for instance how many milliamperes are required to produce a contraction in a certain muscle. He had recently made some preliminary experiments in that direction with the cathodic closure and the anodic closure; he thought a certain number of observations on normal muscles were necessary to determine the number of milliamperes required to produce a contraction.

Dr. Jacoby, on behalf of the Committee, replied as follows: I feel that the fine idea of the Committee is lost to view. It was on dosage, not galvanometers, that it was formed. It would be a work of years and years and not the work of a committee of three men alone. Remarks as to the covering of electrodes did not enter into our consideration. Ohm's law covers that. If the resistance is increased, current strength must be increased. The reason that no particular galvanometer was recommended was because they did not care to recommend any particular instrument maker; all galvanometers have their objections; this must be left to individual choice. It would be a difficult matter to find a standard galvanometer, it would be difficult to find one remaining the same after a year. The best and most delicate he had ever used changed. They are subject to magnetic influences. As regards the amount of current strength required to effect a certain result; if the Committee were to inform the Association that a certain number of milliamperes would cure a certain disease, it would be only individual experience. As regards the question of electrical dosage, there again you will obtain a contraction with the danger of the same result. He did not think absolutely normal muscles would give you similar contractions. The recommendations of the Committee are a plea for accuracy, to use the milliampere as has been done; but when you do, describe the amount of current used, give the number of milliamperes and style of electrode used.

Dr. Amidon then showed a photograph sent by Dr. Correll, of Zurich, of a microcephalic girl who had three sisters also afflicted in the same manner, and who had since died. The parents were natural in appearance and enjoyed good health.

Dr. Wilder stated that he wished to retract what he had said yesterday in relation to the brain of the Chinaman: he had since had an opportunity of carefully examining the same, and thought it the most remarkable brain he had ever examined, although there was nothing to point to its Mongolian origin. It presented some remarkable features, and in a great many ways pointed to an ape ancestry.

NOTES ON THE BRAIN. AN ADDITIONAL CASE OF INDEPENDENCE OF THE PAR-OCCIPITAL FISSURE,

by Dr. B. G. Wilder.

The writer, in his recent paper on the par-occipital fissure stated that among forty-three reliable specimens and figures accessible to him, the par-occipital was continuous with the parietal in twenty-one, and independent in twenty-two.

The brain of a negro child at birth, lately prepared by him, had two fissures wholly independent on the right, and barely united by a shallow junction on the left side.

The ental correlative of the occipital fissure in an early fœtus — in a fœtus estimated to be about three months of age — as shown in the accompanying photograph. Opposite the occipital fissure there was a distinct ental ridge, so that the entire thickness of the wall was there folded. A similar ridge is figured by Tiedman but not named or described; by further observations he could not determine upon as to whether it disappears in the adult or persists as a more or less distinct elevation known as the bulbous cornu posterioris or eminentia splenalis. Even if transitory, it adds another to the list of total fissures, including the calcarine, hippocampal, collateral and Sylvian.

POINTS ILLUSTRATED BY THE TRANSECTION OF THE FŒTAL BRAIN.

Six points of morphological interest we note, most of them indicating that the thalami increase in width as development proceeds, so that in the adult human brain they form, or seem to form, part of the floor of the proiœtes or lateral ventricles, which is not the case in other mammals, excepting, perhaps, the primates.

Dr. Mills then presented the brain of a baboon and of a negro sent by Dr. Formad, of Philadelphia.

DR. LEONARD G. WEBER, of New York, read a paper on

SOME AFFECTIONS OF THE NERVOUS SYSTEM ASSOCIATED WITH TUBERCULOSIS.

DR. WEBER remarked that in phthisis there was a condition of the mind in which cheerfulness predominated, but there was one in which the most gloomy thoughts were indulged in, frequently ending in insanity, and it was of this latter that he wished to speak. He illustrated his remarks with clear but somewhat lengthy histories of two cases, describing at length the well-known symptoms involved; he thought that rest-hygiene, somewhat like Dr. Mitchell's plan, was the proper treatment, but in these cases the difficulty was to make them rest, as it would be an extremely difficult matter to confine such patients to bed. He thought that in those cases where mental aberration occurred it was desirable to examine the lungs, as often the mental symptoms appeared long before any positive diagnosis of phthisis could be made.

DR. GRAY remarked that these cases had puzzled him sometimes, so much so, that he had sent his patients to a specialist in auscultation for an examination of the lungs. A case was quoted by him in which the mental symptoms predominated, and a consultation was called as to what really was the trouble; the patient died. At the autopsy, signs of tuberculosis were discovered. He thought Dr. Weber had looked at the prognosis of these cases in a rather too despondent manner, as he knew of several cases which had recovered and enjoyed excellent health. As to treatment, he agreed with Dr. Weber; the point is to secure absolute restriction of all expenditure of energy, giving them the largest quantity of food they can take.

DR. WEBER replied he was glad to hear hygienic measures emphasized, and also the great point of diet discussed; that in Germany this was very fully realized, and he had himself, while visiting there, seen it carried out with excellent results.

DR. VAN BIBBER, of Baltimore, stated that he was in the habit of seeing a great many cases of melancholia, and that he made it a custom to always examine the lungs.

DR. PARSONS, of Sing Sing, N. Y., stated that he had had charge of a large number of cases of melancholia, and he had noticed the frequency with which phthisis was associated with it, and he had observed that frequently the disease of the lungs would run into the second, and even the third stage without objective symptoms.

AFTERNOON SESSION.

DR. WILDER exhibited a frog which he had decerebrized more than seven months ago. The wound healed perfectly, and the animal has enjoyed good health ever since; the operation was performed on December 9th, 1885. A minnow or piece of fish is given to him twice a week, but it requires two persons to feed him, as one has to open his mouth, and the other puts the food in, and here a curious phenomenon presents itself — that if a piece of the minnow's tail projects from his mouth, the frog, while making an effort to swallow the fish, will, with its fore-feet, endeavor to pull the fish out of its mouth. The movements of the frog also are self-induced, for after remaining in one position for some time, he will slightly change his position. If placed upon a convex surface, and this be slightly revolved, he will endeavor to balance himself. The writer sometimes, while carefully observing him, would notice that he would wink with only one eye, but, when irritated, he would wink both eyes. He also wondered whether the animal ever slept, as on the least jar, when apparently asleep, he would instantly open both eyes. (The frog was then fed before the meeting, and exhibited the phenomenon described). Dr. Wilder remarked that he would like to know if a frog, under these conditions, could be educated. Just before coming into the meeting, while removing the frog from his box, one of his hind legs was accidentally broken, but it does not appear to cause him any inconvenience, and apparently no pain is felt. This frog also can be laid upon its back, and will remain there without any aid of mesmerism. The question also occurred to him whether this frog was capable of procreating his species.

DR. GRAY asked if he had ever hypnotized that frog.

DR. WILDER replied he had not.

DR. MILLS thought it would not have that part of the brain to be hypnotized.

DR. SACHS stated that he was in Gault's Laboratory for some time, and saw frequent exhibitions of frogs, but nothing was removed; the parts were simply severed. He thought Dr. Wilder's method more thorough, and was surprised to see the frog live so long; he then asked Dr. Wilder if he had ever put a block of wood in front of the frog and then irritated it, to see if it would jump over it or avoid the obstacle.

DR. WILDER replied that he had not.

MR. JASTROW, of the Johns Hopkins University, stated that he had a series of frogs at one time. First, normal; second, the same as this one; third, the optic lobes were also removed; fourth had everything removed. He had found that the more you removed, the more readily would the frog remain upon its back.

DR. WILDER remarked that when the parts were severed subcutaneously, there might be a question whether union did not occur.

DR. ZENNER stated that, in the hands of some experimenters, there had never been reproduction in the cord, but he did not know how it was in the brain.

DR. GRAY suggested applying a little acetic acid to one of the frog's legs, to see if he would try to brush it away.

DR. WILDER replied that he had not neglected to do so, and with the usual result.

MR. JASTROW said he found a frog that had lost one leg; he applied a little acid to its body; first the animal tried to brush it off with his sound leg, and afterwards with the stump of the other.

(To be continued.)

— According to a recent writer in the *Nineteenth Century*, the average number of days of sickness of the better class of Englishmen in middle life are about four days per annum. According to statistics derived some years since from the records of the mutual benevolent societies, whose members are drawn from classes not well situated in a hygienic point of view, and who report themselves as "sick," when having only local injuries incapacitating them from use of the hands, the number of days of illness in the lower classes, among men of middle age, was six days per annum.

Medical and Surgical Journal.

THURSDAY, AUGUST 19, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & Co., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

LITHÆMIA.

THE term lithæmia is now applied to a morbid complexus in which there are various nervous symptoms (vertigo, certain obscure neuralgic pains, palpitations, cramps and muscular twitchings, lassitude and irritability of temper) associated with an excess of urates, and frequently of oxalates in the urine. In accordance with modern views of the metabolism of albuminoids, the liver has been supposed to be the principal source of uric acid production, as well as the seat of that "metabolic neurosis" which finds expression in lithæmia, oxaluria, and glycosuria. In short, there has been a partial return (with clearer notions, however,) to the old humoral pathology, which ascribed a whole series of disorders to peccant principles in the blood, and we are now taught, as a deduction from important experimental facts, that there is a gouty diathesis, which, in its grave form, is gout, in its mild form is lithæmia.

Public attention was called to the "nervous symptoms" of lithæmia by an article by Dr. Da Costa in the *American Journal of Medical Sciences* for October, 1881, and subsequent articles by Lyman in this JOURNAL,[1] by Bartholow in "Pepper's System of Medicine," by Dana in the *Medical Record*, have tended to confirm or qualify Da Costa's views. Da Costa and Lyman have laid much stress on vertigo as a symptom of lithæmia, and the disappearance of this symptom under careful dieting, with exercise and a suitable eliminative treatment. Bartholow includes under the symptoms of lithæmia, derangements of the digestive organs and liver, of the circulation and nervous system. The subjects of lithæmia have the symptomatology of gastro-intestinal catarrh, with headache, frontal and occipital, dizziness, tinnitus aurium, nervous irritability, and despondency; they are subject to neuralgic attacks, have aching in their limbs, and more or less burning in the palms and soles.[2] Bartholow explains these symptoms as due to "deficient oxidation" of urea in the liver. "When albuminoid matters are taken in excess of the power of the system to convert them, or when the supply of oxygen to the blood is deficient from any cause, urea is not formed, but uric acid, and urates are abundantly excreted by the kidneys;" this excess of urates constitutes lithæmia.

At a meeting of the Practitioners' Society of New York, December 4, 1885, there was an interesting discussion of a paper by Dr. C. L. Dana, on the "Relation of Lithæmia, Oxaluria, and Phosphaturia to Nervous Symptoms."[3] Dr. Dana took the ground that there is no such thing as a lithæmic or uric-acid diathesis. There are, however, morbid conditions of the nervous system which are associated with excessive acidity of the urine, and excess of uric acid in the urine. The morbid nervous symptoms in these cases are those of gastric neurasthenia, lighter forms of nervous irritation, great nervous irritability, vertigo, bad sleep, hypochondriasis, etc. The lithæmic state is one allied to gout and rheumatism, rather than identical with either. Besides the ordinary and recognized divisions of neuroses — motor and vaso-motor, trophic and secretory, sensory — Dr. Dana would make a fourth class, the *metabolic neuroses*, glycosuria and lithæmia being included under this head.

In the discussion which followed, Dr. W. H. Draper expressed the belief that the lithæmic state (which he was inclined to regard as a diathesis whose aggravated condition finds expression in gout, rheumatism, and diabetes), is often responsible for chronic catarrhal affections of the gastro-intestinal tract, and even of the respiratory tract. The nervous disturbances he attributed to vaso-motor derangements provoked by the poisoned condition of the blood. Dr. E. D. Hudson, Jr., had come to the conclusion that the majority of neurasthenic cases were of lithæmic origin, and that the liver was the organ especially at fault. It seemed to him evident that most of these cases occurred in persons of rheumatic or gouty diathesis, and he had observed the transition, in a patient, from acute and sub-acute rheumatism to lithæmic symptoms. Dr. G. B. Fowler was disposed to refer lithæmia and oxaluria to interference with digestion, and imperfect oxidation of albuminoids.

Dr. A. A. Smith stated that he had been led to regard deranged states of the alimentary canal, and especially of the liver as at the bottom of all symptoms included under the names lithæmia, phosphaturia, oxaluria. When he became actively engaged in practice he found that his teachers had paid too little respect to the liver. His own respect for it was constantly increasing. Even in malarial poisoning he would give a cholagogue, not before giving quinine, but in connection with it, in short, in most of the cases under consideration persistent treatment directed to the liver would effect a cure.

In this discussion there was a striking unanimity as to the value of a diet in lithæmia largely nitrogenous; the withdrawal of carbo-hydrates and saccharine foods; the use of alkaline remedies, and mild cholagogues, and the administration of nerve tonics such as strychnia.

[1] G. H. Lyman in Boston Medical and Surgical Journal, Dec. 13th, 1883.

[2] Bartholow in "Pepper's System of Medicine," Vol. II, p. 970.

[3] Medical Record, January 16, 1886.

The discussion at the meeting of the Association of American Physicians at Washington in June last [4] on the question, "Does the Present State of Knowledge justify a Clinical and Pathological Correlation of Rheumatism, Gout, Diabetes and Chronic Bright's Disease," was opened by Drs. James Tyson and W. H. Draper, and was participated in by Drs. J. T. Dana, Horatio Wood, A. L. Loomis, William Pepper, A. Jacobi, E. G. Janeway and others. This discussion was so recently reported that it is unnecessary to more than refer to it. Those interested will find there the present mental attitude toward this subject of some of the leading clinicians and pathologists in the United States.

The problem of how from retrograde food or tissue elements, uric acid may be generated in such excess as to poison the economy has of late occupied the earnest attention of physiological chemists, notably Schultzer, Nenki, Salkowski, Hoppe-Seyler and Latham. It may be that valuable results, with an important bearing on the therapeutics of the future have been attained. The metabolism is of an exceedingly complicated nature, with what success the formula has been worked out may be judged by the synopsis given below of Latham's valuable contribution in the London *Lancet* (Vol. 1, 1886):

In order to study the changes which take place in the tissues in rheumatism, gout and diabetes owing to abnormal metabolism, the first consideration is to determine as far as it may be possible the structure of the molecules of living tissues, and then what changes take place on the death of the molecule. Lieberkühn gives the formula of albumen as $C_{72}H_{112}N_{18}O_{22}S$, and from the decomposition of albumen may be obtained aspartic acid, glutamic acid, acids of the lactic acid series, ammonia, glycocine (glycocol or amido-acetic acid), leucine, tyrosine, and other amido-acids. It is well known that lactic acid and the amido-acids can be prepared from a particular series of cyanogen compounds, the cyanalcohols, of which the type is $C_nH_{2n}\begin{cases}OH\\CN\end{cases}$. These cyan alcohols are unstable bodies, and possess some of the properties of living tissue, namely, that of undergoing intramolecular change, and also that of condensation.

Further, the cyan alcohols can be formed from the amido-acids as leucine and tyrosine, which exist in the intestine, and which are also converted into urea in the liver. (In yellow atrophy of the liver, urea disappears from the urine and is replaced by leucine and tyrosine). In the normal condition the urea which is excreted by the kidneys, enters the circulation with the blood which issues from the liver.

Pflüger attributed the functional metabolism of protoplasm, by which energy is set free, to the conversion of unstable cyanogen compounds to less energetic, stable amines, of which Wöhler's conversion of ammonium cyanate into urea by heating is a type: ammonium cyanate, CNO NH_4 is a type of living protoplasm, urea $CO(NH_2)_2$ of dead protoplasm.

By combination of amido-acids with dehydration, molecules would be formed containing the group CNOH, characteristic of cyanalcohols, this group arising from the dehydration of the acid-group CO·OH and the amido-group NH_2. Since, further, this group CNOH possesses a marked tendency to condense — as CNOH, cyanic acid to $(CNOH)_3$ cyanuric acid — by combining different cyanalcohols with tyrosine, we might have a molecule

$$C_6H_3\begin{cases}OH\\SO_2OH\\CH\cdot CN\cdot(CH_2\cdot CNOH)_3\cdot(C_6H_4\cdot CNOH)_3\cdot(C_6H_6\cdot CNOH)_x(C_6H_4CNOH)_y(C_6H_{22}CNOH)_zOH\end{cases}$$ or

$$C_{72}H_{110}N_{18}O_{22}S$$

which differs by H_2 only from Lieberkühn's formula for albumen. When such a molecule, held together by a force vital or otherwise, is decomposed, the CNOH group would be broken up and among the decomposition products might be acids of the lactic acid series, ammonia, glycocine, leucine, tyrosine, creatine, creatinine, urea, and carbonic acid, the products depending upon the mode of decomposition.

In the case of rheumatism and gout, the morbid product is uric acid, and not as formerly supposed, lactic acid, which is present merely as a result of the decomposition spoken of. The uric acid is due to defective metabolism and is a condensation product of the amido-acid glycocine, with urea, a condensation which may be artificially carried out. The process is as follows: The glycocholic acid (a compound of glycocine and cholic acid) of the bile enters the intestine and after it has served its purpose in digestion, the glycosine is returned to the blood. This with other amido bodies as leucine and possibly tyrosine, the products of digestion of albuminous food, is carried by the portal vein to the liver, and there converted into urea. When, however, this metabolism of glycocine in the liver is interrupted, whilst leucine and tyrosine still undergo normal changes into urea, we have in the liver glycocine and urea, which by dehydration become hydantoin, and this being easily soluble, passes into the circulation. In confirmation of this we have the experiments of Schiffer, in which, after the administration of sarcosine (methyl glycocine), methyl hydantoin was found in the urine. The hydantoin reaches the kidneys and is there condensed with urea (or biuret, a condensed urea) into ammonium urate. If the kidneys are sound, unless in large excess it will be excreted as fast as formed, and there will be little if any overflow into the circulation; when the urine is alkaline it will appear as urate of ammonium, sodium, etc., if other acids are formed at the same time and eliminated by the kidneys, the uric acid will according to the amount give rise to gravel, renal or vesical calculi. But if the kidneys become weakened or overflow, a portion of the urate will pass on into the circulation, and meeting the soda of the blood will be converted into sodium urate, in which form, it is deposited about the gouty joints; and being toxic it will act upon some portion of the nervous system, causing irritability, gloom, cephalagia, vertigo, palpitations, etc.

If uric acid is the poison of rheumatism and gout, the treatment should aim to prevent its formation and to promote its elimination. If the formation can be prevented, the kidneys will in time accomplish the elimination. Since the formation of uric acid depends upon glycocine, by seizing and eliminating this we may accomplish the end. When benzoic acid is introduced into the system of a mammal, it appears in the urine as hippuric acid, which is a condensation product of benzoic acid and glycocine. We can conceive in this case that the benzoic acid may combine directly with the glycocine to form hippuric acid, $C_6H_5\cdot CO\cdot NH\ CH_2\cdot COOH$: or that the benzoic acid unites with the cyanalcohol $CH_2\cdot CNOH$, which is the antecedent of glycocine, forming living hippuric acid, C_6H_5 (C N OH) $CH_2\cdot COOH$. When instead of benzoic acid, salicylic acid is used, the result is similar, salicylurie acid being formed. When the function of the liver is so interfered with that there is imperfect metabolism of glucose in passing through the organ, we have glycosuria, in which we are sure to witness marked mitigation by a careful diet, and abstention from saccharine and starchy food. But in other cases the diet seems to have much less effect in controlling the symptoms. If in the decomposition of albumen before spoken of, the group $CH_2\begin{cases}OH\\CN\end{cases}$ should be detached and hydrated to glycollic acid $CH_2\begin{cases}OH\\COOH\end{cases}$, and only partially oxidized, there would be formed carbonic acid, water, and methyl aldehyde HCHO, which as in plants might condense to glucose.

Should the group $C_2H_4\begin{cases}OH\\CN\end{cases}$ be similarly hydrated to lactic acid, and partially oxidized, we should have aldehyde CH_3CHO, which by condensation would become paraldehyde $(CH_3CHO)_3$, a remedy recently introduced as a hypnotic, and hence the drowsiness which appears in some stages of diabetes.

And again, the group $C_3H_6\begin{cases}OH\\CN\end{cases}$ would yield similarly acetone $CO(CH_3)_2$, which appears in the urine toward the termination of the disease.

Researches such as these must still be regarded as mainly speculative, though interesting and suggestive, and doubtless giving unmistakable indications as to the direction in which chemical pathology is tending.

[4] Journal, June 30th, July 6th.

SYPHILIS IN COREA.

We have previously on more than one occasion quoted the Medical Reports of the Imperial Maritime Customs of China. Their object is to procure and disseminate information in regard to disease among foreigners and natives in China. The last number of the series contains a report from Dr. H. N. Allen, on the health of Seoul, the capital of Corea, which is exceedingly interesting as an account of a little-known nation, but is most striking in the prominent part which it attributes to syphilis in the native pathology. Dr. Allen does not so state but it is very evident from his account that practically no treatment is available for this disease except through foreigners, so that his report may serve to give us an idea of the natural history of a nation in which syphilis is not only allowed to run its course unchecked, either by governmental regulation or by medical treatment, but is fostered by the habits of the people.

The people are married early and plural marriage is the common rule. Concubinage is recognized and a class of "dancing girl" prostitutes is largely blamed for the spread of syphilitic affections and gonorrhœa. Chancroidal ulcers about the anus occurring in boys led to the discovery of unnatural practices which the report mentions but without details. "Gonorrhœa seems as inevitable as ague and does not alarm the patient. The people distinguish between the various veneral troubles and have separate names for gonorrhœa, syphilis, and the primary sore." The discharge and painful urination in gonorrhœa is all that they wish treatment for; the presence of gleet seems a matter of little concern to them. "Chancres in all stages" are frequently seen; chancroids more often. Constitutional syphilis is known as the Chinese disease, and is almost a constant factor which must be considered in making up nearly every diagnosis. It is known to be the cause of the frequent abortions and the children that survive have very often ugly notched teeth.

Leprosy is also abundant, occurring in all its forms. Many of the patients are beggars who are not well posted in their family history, but from the disconnected accounts it seems probable to Dr. Allen that the disease is often hereditary. Leprosy and syphilis are often co-existent and iodide of potassium and iron worked quite a change up to a certain point. This has given rise to a report that foreign medicines will cure leprosy and as a result victims come from distant provinces with large certificates bearing the stamp of the various governors through whose territory they have passed to the effect that the bearer is worthy, etc. The report makes mention of certain cases in which the frontal bone is carious and the nose eaten away. The diagnosis in these nose cases proved difficult and the question between syphilis and leprosy was left to treatment.

Eunuchs are very commonly met; they are intended for service at the palace, yet they usually have their own homes and women. A Eunuch's "compound" is known by its usually having only one gate, instead of the usual gate for men and another for women. This is said to be a necessary precaution for keeping the women in as they do not like their masters and are apt to run away. One case of gonorrhœa presented itself in the person of a eunuch. The operation of castration usually consists in ablation of the testes only, but in some cases all the appendages are said to be removed.

Malaria occurs in all its forms, tertian, quartan, and quotidian; double quartern and double quotidian; "in fact the patients seem so over-charged with the poison that they only come out of one paroxysm to go into another." Very naturally masked forms also occur as brow ague, when syphilis and malaria sometimes join forces and pains occur every other night, in which cases quinine and the iodide need to be united.

Appended to the report is a list of the out-patients treated during the first six months after the establishment of the hospital at Seoul. It bears evidence of being the work of a man more interested in his cases than in the compilation of statistics but its figures are very interesting. It shows a total of 7,234 cases: of these, chancre and syphilis count up 868, and other headings must contain many cases of the same nature, as nocturnal pains, 50; necrosis frontal bone, 6; iritis, 6; enlarged cervical glands, 176; ulcerated throat, 60; In addition there were chancroid, 200, gonorrhœa, 196, gleet, 47.

MEDICAL NOTES.

— Dr. George Sturge in a letter to the *British Medical Journal*, lamenting the inadequacy of the Hospital Sunday offerings to support the expenses of the London Hospitals, says that these institutions altogether expend the sum of £10,000 annually for alcoholic liquors, of which a large portion is consumed by the medical staff.

— During the past year, wild beasts and snakes were unusually destructive to human life in the Central Provinces of India, there having been an increase of 262 in the number of persons killed, as compared with the preceding year. Of wild beasts, tigers, of course, were the most destructive, their victims numbering 110, against 98 in 1884, while the number of tigers killed was only 221, against 260. The death from snake-bite last year amounted to 1,066, against 797 in 1884, while only 1,997 snakes were killed, as compared with 2,378 the previous year.

— At this season of the year the *Northwestern Lancet* opportunely calls attention to the value of watermelons as a diuretic, because at this time the fruit can be obtained at the greatest advantage. There is, however, a preparation called honey of watermelon whose diuretic action is most striking. A Russian physician has recently made experiments both with fresh juice and the syrup, and has been able to increase the daily flow of urine by three or four times. The treatment is well worth trying, not only in dropsies from various

causes but in gonorrhœa, cystitis, and other affections of the genito-urinary tract where it is desired to produce an abundant and bland urine. The peasants of Russia have long know this remedy and used it with good success in the classes of affections named.

— A contemporary quotes the following story from "Lockhart's Life of Scott": It happened at a small country town in the North of England that Scott suddenly required medical advice for one of his servants, and on inquiring if there was any doctor at the place, was told that there were two — one long established, and the other a new-comer. The latter gentleman, being luckily found at home, made his appearance — a grave, sagacious-looking personage, attired in black, with a shovel hat, in whom, to his utter astonishment, Sir Walter recognized a Scotch blacksmith, who had formerly practised with tolerable success as a veterinary operator in the neighborhood of Ashestiel. "How in all the world," exclaimed he, "can it be possible that this is John Lundie?" "In troth is it, your honor, just *a' that's for him.*" "Well, but let us hear; you were a *horse* doctor before; now it seems you are a man doctor; how do you get on?" "Ou, just extraordinar' weel; for your honor maun ken my practice is vera sure and orthodox. I depend entirely upon twa *simples.*" "And what may their names be? Perhaps it is a secret." "I'll tell your honor;" in a low tone, "my twa simples are just *laudamy* and *calamy!*" "Simples with a vengeance!" replied Scott. "But, John, do you never happen to *kill* any of your patients?" "Kill? Ou ay, may be sae! Whiles they die and whiles no; but it's the will of Providence. *Ony how, your honor, it wad be lang before it makes up for Flodden!*"

NEW YORK.

— From the books recording the financial transactions of the Croton Aqueduct Commissioners, which have just been officially examined by the Commissioners of Accounts, it appears that the total expenditures from October, 1883, to August, 1886, amounted to $5,174,574.

Miscellany.

OPERATION OF THE ACTS RELATIVE TO THE ADULTERATION OF FOOD AND DRUGS IN MASSACHUSETTS.

In a circular lately issued by the Massachusetts Board of Health, the following articles are specified as having been found by the chemists of the Board to be especially liable to adulteration:

Food. *Form of Adulteration.* Milk: addition of water or coloring matter, and abstraction of cream. Butter: substitution of foreign fats, and addition of coloring matter. Spices: addition of starch and other foreign powders. Especially true of pepper and mustard. Cream of Tartar: substitution of starch, gypsum, and other cheaper substances. Baking Powders: alum and other injurious ingredients. Baking powders have no legal standard other than that of freedom from harmful ingredients. Lard: presence of cheaper fats and oils. Olive Oil: substitution of cheaper oils. Jellies and Preserved Fruits: substitution of cheaper fruits, and addition of coloring matter. Vinegar: absence of the required amount of acetic acid, and addition of coloring matter. Honey: substitution of cane sugar, glucose, and other substances. Molasses: addition of glucose, presence of tin or other foreign substances. Sugar: glucose, poisonous coloring matter. Maple Sugar and Syrup: glucose. Confectionery: terra-alba, poisonous coloring matter, fusel oil, arsenical wrappers, etc. Coffee: mixture or substitution of various cheaper substances. Canned Fruits, Vegetables, and Meats: metallic poisons.

Drugs. *Form of Adulteration.* Opium and its preparations, especially powdered Opium and Tincture of Opium: deficiency in the required strength of morphia. Cinchona, Quinine, and its preparations, especially the Citrate of Iron and Quinine: deficiency in the required amount of quinine. Quinine Pills: deficiency in weight. Compound Spirits of Ether [Hoffmann's Anodyne]: absence of its most important ingredient, the ethereal oil, or substitution thereof. Spirits of Nitrous Ether [sweet spirits of nitre]: deficiency in ethyl nitrite. Salts of Bismuth: excess of arsenic. Tincture of Iodine: deficiency in iodine. Iodide of Potassium: excess of chloride, or other impurities. Bitartrate of Potassium: excess of lime or other impurities, and substitution of starch and other ingredients. Jalap: deficiency in required strength. Cochineal: loaded with heavy foreign powders. Essential Oils: adulteration with turpentine. Pharmacopœal Wines and Liquors: excess or deficiency in required strength of alcohol, and excess in solid residue, addition of water, alcohol, or sugar.

Since the enactment of the laws of 1882 and the succeeding years providing for the inspection of Food and Drugs by the State Board of Health, 175 complaints have been entered in the Courts, for the violation of such laws in forty or more cities and towns of this Commonwealth.

OBITUARY. DR. FRANK HASTINGS HAMILTON.

The eminent surgeon, Dr. Frank Hastings Hamilton, who has been in bad health for the past two years, died at his residence in 324 Street, on August 11th. During his last illness he was attended by Drs. Dammainville and Lansing, with Dr. Austin Flint as consultant.

Dr. Hamilton was born at Wilmington, Vermont, September 10th, 1813, and was graduated from the Medical Department of the University of Pennsylvania at the early age of twenty. After remaining for a short time at his home in Vermont, he commenced practice at Auburn, New York, where he soon won an enviable reputation as a surgeon. Five years after receiving his medical degree he was appointed Professor of Surgery in the Fairfield (New York) Medical School, and one year later he gave up this position to accept a similar one at the Geneva (New York) school. He remained at Geneva for nearly four years, and then went to Buffalo; where, together with the late Drs. Austin Flint and James P. White, he was instrumental in organizing the present medical department of the University of Buffalo. From 1846 to 1860 he remained Professor of Surgery, constantly adding to his laurels as a distinguished surgeon and teacher. In 1860 he accepted the professorship of surgery in the Long Island College Hospital, and removed to Brooklyn; but scarcely had he settled in his new home when the Civil War broke out, and he entered the army as surgeon of the 31st Regiment New York Volunteers. Between his entrance into the military service and 1863 he was successively promoted to the grades of Brigade Surgeon, Corps Surgeon, under Gen. Keyes, and Medical Inspector of the United States Army. After leaving the army he came to New York to reside, and was one of the founders of Bellevue Hospital Medical College; in which school he occupied the Chair of Surgery until 1875; when he resigned. He still retained his position as one of the surgeons to Bellevue

Hospital, however, and continued to hold surgical clinics, which were largely attended.

Not only as a practical surgeon and a teacher of surgery, but also as a writer, Dr. Hamilton attained the highest eminence. His standard work on "Fractures and Dislocations," has gone through seven editions, and has been translated into both French and German. Among his other widely-known works, in addition to a large number of valuable monographs, are "Prognosis in Fractures," "Treatise on Military Surgery," "New Views on Provisional Callus," and "Treatise on the Principles and Practise of Surgery." The latter (published originally in 1872) was the work in which he took the greatest pride, and he felt that the crowning labor of his industrious life was the completion of the third edition of the book, which was issued only a few weeks since. He was also highly distinguished as an inventor of surgical appliances, and one of the most useful of his achievements in this field was the introduction of gutta-percha for splints for application to irregular surfaces.

Almost immediately after President Garfield was shot, Dr. Hamilton was summoned to his bedside at the particular request of Mrs. Garfield, who was naturally anxious to secure the most eminent surgical talent in the country, and he went on to Washington by a special train; remaining almost constantly in attendance upon the wounded president until his death at Long Branch.

Dr. Hamilton was consulting surgeon to St. Elizabeth's Hospital and a large number of other medical institutions in New York, and at various times was President of the Medical Society of the State of New York, the New York Pathological Society, the Society of Medical Jurisprudence and State Medicine, and other scientific bodies.

Dr. Hamilton was twice married; his first wife, whom he married in 1834, being Miss Mary Virginia McMurran, of Virginia, and his second, whom he married in 1840, Miss Mary Hart, of Oswego, New York; the latter died about a year ago. Two children survive him, Col. T. B. Hamilton and Mary, wife of Daniel Davis, Esq. The funeral services were held at his residence in New York, August 14th, and the interment was at the Sleepy Hollow Cemetery at Tarrytown-on-the-Hudson.

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 7, 1886.

Deaths reported 2,604: under five years of age 1,322: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 887, consumption 294, lung diseases 109, diarrhœal diseases 645, diphtheria and croup 93, typhoid fever 51, whooping-cough 27, malarial fever 27, scarlet fever 21, measles 11, cerebro-spinal meningitis nine, puerperal fever three. From whooping-cough, New York 11, Brooklyn eight, Pittsburgh five, Boston, Charleston and Newton one each. From malarial fevers, New Orleans nine, Brooklyn six, New York four, Charleston two, Philadelphia, Nashville, Springfield and Northampton one each. From scarlet fever, Brooklyn seven, Pittsburgh five, New York four, Philadelphia three, Baltimore and Providence one each. From measles, New York eight, Brooklyn, Cambridge and Lynn, one each. From cerebro-spinal meningitis, New York five, Philadelphia three, Lowell one. From puerperal fever, New York, Brooklyn, and District of Columbia one each.

In the 22 cities and greater towns of Massachusetts, with a population of 958,050 (population of the State 1,941,465), the total death-rate for the week was 25.02 against 26.39 and 24.27 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending July 24th the death-rate was 20.2. Deaths reported 3,521: infants under one year of age 1,296; acute diseases of the respiratory organs (London) 163, diarrhœa 505, measles 86, whooping-cough 66, fever 36, scarlet fever 36, diphtheria 25.

The death-rates ranged from 7.8 in Wolverhampton to 24.6 in Birkenhead; Birmingham 18.1; Blackburn 21.4; Hull 14.2; Leeds 17.9; Leicester 24.3; Liverpool 20.6; London 21.6; Manchester 24.2; Nottingham 15.3; Sheffield 16.6.

In Edinburgh 16.8; Glasgow 23.6; Dublin 21.0.

For the week ending July 17th, in the Swiss towns, there were 41 deaths from consumption, lung diseases 22, whooping-cough five, typhoid fever four, small-pox two, diphtheria and croup one.

The death-rates were: at Zurich 11.5; Geneva 13.1; Basle 17.1; Berne 18.2.

The meteorological record for week ending August 7, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, Aug. 7, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 7, 1886, TO AUGUST 13, 1886.

WOLVESTON, WM. D., major and surgeon. Granted one month's leave of absence on or about August 15, 1886. S. O. 104, Division of the Atlantic, August 7, 1886.

BENTLEY, EDWIN, major and surgeon. Ordered from Department Texas to Department East.

APPEL, D. M., captain and assistant surgeon. Ordered from Department East to Department Texas. S. O. 179, A. G. O., August 4, 1886.

LORING, LEONARD Y., captain and assistant surgeon. Granted leave of absence for one month, on surgeon's certificate of disability, with permission to apply for an extension of two months. S. O. 59, Division of the Pacific, August 2, 1886.

ADAIR, GEO. W., captain and assistant surgeon. Ordered for duty as post-surgeon, Fort Brady, Michigan.

GANDY, CHAS. M., first lieutenant and assistant surgeon. Granted leave of absence for one month, with permission to apply for one month's extension. S. O. 103, Division of the Atlantic, August 6, 1886.

MERRILL, JAMES C., captain and assistant surgeon. Assigned to duty as post-surgeon at Fort Klamath, Oregon. S. O. 120, Department of Colorado, July 30, 1886.

BENHAM, ROBERT B., captain and assistant surgeon. Relieved from temporary duty at Fort Omaha, Neb, and ordered to Fort Bridger, Wyo. S. O. 97, Department of Platte, August 5, 1886.

RETIRED.

MURRAY, ROBERT, brigadier-general and surgeon-general, August 6, 1886.

APPOINTMENTS.

To be assistant surgeons with the rank of first lieutenant:

HARRIS, HENRY S. T., January 5, 1886.

WOOD, LEONARD, January 5, 1886.

BANISTER, WILLIAM B, January 26, 1886.

MASON, CHARLES F., May 5, 1886.

PROMOTIONS.

To be surgeon with the rank of major:

BARTHOLF, JOHN H., captain and assistant surgeon, January 4, 1886.

KIMBALL, JAMES P., captain and assistant surgeon, January 24, 1886.

(Mem. A. G. O., August 2, 1886.)

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE HOSPITAL SERVICE FOR THE WEEK ENDING AUGUST 7, 1886.

HUTTON, W. H. H., surgeon. To proceed to Key West, Fla., for temporary duty, August 7, 1886.

BEVAN, A. D., assistant surgeon. Ordered to examination for promotion, August, 1886.

WILLIAMS, L. L., assistant surgeon. When relieved at Buffalo, New York, to proceed to Mobile, Ala., for temporary duty, August 2, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING AUGUST 14, 1886.

WALTON, THOMAS C., surgeon. To remain on present duty until September 1, 1887.

WHITE, C. H., passed assistant surgeon. To remain on present duty until August 21, 1887.

RUSH, C. W., passed assistant surgeon. Authorized to delay ten days, under orders to Sitka, Alaska.

LUMSDEN, G. P., passed assistant surgeon. Ordered to Hospital, Mare Island, Cal.

BALDWIN, L. B., passed assistant surgeon. Ordered to the United States Steamship "Ranger."

NEILSON, J. L., surgeon. Detached from the United States Steamship "Ranger," to proceed home and wait orders.

BOOKS AND PAMPHLETS RECEIVED.

The Pathology and Treatment of Dropsy. By James Barr, M.D., L.R.C.S., Edin., Physician to the Stanley Hospital, Liverpool; Medical Officer to H. M. Prison, Kirkdale. (Reprint.)

Meconeuropathia. By C. H. Hughes, M.D., St. Louis, Mo. (Reprint.)

Positive Medication. A Pamphlet on Alkatrits, Alkametric Granules, and Alkadermic Pellets. New Forms of Medication in which the Potent Isolated Principles of Drugs may be administered so as to produce more Certain and Precise Results than hitherto have been obtained from the usual Forms in which Medicines have been dispensed. Also upon Alkassayed Fluids, a Class of Superior Assayed Fluid Extracts, each being adjusted to a Uniform Standard of Strength. Detroit, Mich.: Frederick Stearns & Co.

The Value of the Knee Phenomenon in the Diagnosis of Diseases of the Nervous System. By Philip Zenner, A.M., M.D., Lecturer on Diseases of the Nervous System in the Medical College of Cincinnati, Ohio. Chicago: 1886. (Reprint.)

The Treatment of Uterine Flexions. By Virgil O. Hardon, M.D., Lecturer on Operative Gynæcology, Southern Medical College, Atlanta, Ga. (Reprint.)

Medical Education and Medical Licensure. An Address delivered before the Twenty-Third University Convocation at Albany, July 9, 1885. By William H. Watson, A.M., M.D., Regent of the University of the State of New York. Albany: Weed, Parsons & Co. 1886. (Reprint.)

THE RELATIONS OF THE INFERIOR THYROID ARTERY AND THE RECURRENT LARYNGEAL NERVE.

BY THOMAS DWIGHT, M.D.,
Parkman Professor of Anatomy at the Harvard Medical School.

TEXT-BOOKS of anatomy say little on this point, which, however, may be of much practical importance. Luschka, Quain, Holden, and Sappey teach that the nerve passes behind the artery. Other authorities give the same impression without distinctly asserting it. Cruveilhier is, I believe, the only one who teaches the contrary. Sappey's account is the most precise one: "In its course, the artery describes two curves: one with the concavity downward and forward, embracing the internal jugular, the common carotid, and the pneumogastric; the other with the concavity looking upward and backward, containing the recurrent nerve."

Having observed some time ago that the relation is not always the same, but that the nerve may be found before the artery, as well as behind it, I began a series of observations, with the help of my assistants, in the anatomical department. I had tabulated the results, and had decided to continue the observations for another year, when I found that this question had been broached in Germany, and as my series is larger than any yet given, I thought it best to publish it now.

The relative position of the nerve and artery may be of interest in œsophagotomy, but it is important chiefly in operations for removal of the whole or a part of the thyroid, and it is in this connection that German observers have studied the question. Wöfler [1] stated that the nerve always passes before a branch of the artery.

Kocher,[2] on the other hand, describes the artery as passing behind the nerve, coming forward on its inner side and hooking over it. Rotter [3] made some fifteen examinations, and found it in a third, as described by Kocher; in a third the artery passed before the nerve. The remainder were not easily classified, as the nerve ran among the branches of the artery. Dr. Streckeiser,[4] in an elaborate paper on the "Morphology of the Thyroid," reports the results of the examination of both sides of fifty-six bodies. He appears, however, to have had chiefly in mind the question whether or not the artery hooked round the nerve, and, if so, to what degree it surrounded it. It is not quite clear, therefore, in how many of his cases the artery passed before or behind the nerve. In thirty-one instances, ten right and twenty-one left, the vessel did not curve round the nerve; and in forty-one cases, nineteen right and twenty-one left, the *ramus perforans* (a branch of the upper division of the inferior thyroid) is the one that makes the curve. This shows that in seventy-two of one hundred and twelve cases, no loop was formed by the main artery. In the remaining forty cases, twenty-seven right and thirteen left, the loop was almost or quite complete. It is probable that the enlarged and more tortuous artery of a diseased gland would be more likely to inclose the nerve in its folds than when the parts are normal; and it must be noted that Streckeiser made his observations at Basle where goitre is very prevalent.

Had I been acquainted earlier with Kocher's views, I should have paid particular attention to this point; as it is, I have endeavored simply to determine whether the artery passed before or behind the nerve, and have disregarded the relations of small branches.

Of the fifty-two bodies examined on both sides, the arrangement was symmetrical in twenty-nine, and the two sides differed in twenty-three. Of the twenty-nine cases in which the sides were alike, the artery was before the nerve in twenty-one, and behind it in eight. Of the other twenty-three, the artery was behind the nerve on the right, and before it on the left in seventeen; the artery was before the nerve on the right, and behind it on the left in three; the artery was either absent, or so small that it did not reach the thyroid in three, two left and one right. On the opposite side of each of these three cases the artery was before the nerve.

In twenty-seven subjects, only one side of the body was examined. On the right, the artery was before the nerve seven times, and behind it six. On the left, the artery was before the nerve ten times, and behind it four.

Adding these observations together, we find that on the right the artery was before the nerve thirty-three times, and behind it thirty-one. On the left, the artery was before the nerve forty-nine times, and behind it fifteen. Three times the artery was absent or very small. It appears, therefore, that as far as we may decide from so small a series, it is an even chance whether the right artery or nerve is in front, and that, on the left, the chances are three to one that the nerve will be behind.

The practical deduction appears to be that when it is necessary to tie the artery near the gland, it should, if possible, be carefully isolated. If the base of an enlarged thyroid be transfixed and ligatured *en masse* it is evident that if the nerve should happen to pass before the artery it would be in danger of being included.

AN EPIDEMIC OF MALARIA IN EASTERN MASSACHUSETTS.[1]

BY ZABDIEL B. ADAMS, M.D., OF FRAMINGHAM.

BETWEEN the years 1876 and 1879, for the purpose of increasing the water-supply in the city of Boston, three large dams were made upon the Sudbury river and one of its tributaries in the town of Framingham. The riparian owners afterwards brought suits against the city on the ground of injury to health. The writer, being summoned as an expert, gave testimony in court, that in his opinion before many years intermittent fever would probably appear in consequence of building these dams. A further study of the subject compels the somewhat humiliating confession that no unimpeachable evidence can be found upon which to base this testimony. It is true that in the summer of 1885, a decided epidemic of malarial fever occurred in South Framingham, and that since that time many cases have appeared in various parts of the town, but there is no clear evidence proving a relation of cause and effect between the creation of these reservoirs and the epidemic of fever.

Almost fifty years ago, Dr. Oliver Wendell Holmes wrote his Boylston Prize Dissertation on intermittent

[1] Read at the Annual Meeting of the Massachusetts Medical Society, June 9, 1886, and recommended for publication by the Society.

fever in New England. This comprised an abstract of all that could be found in the earlier writers regarding the subject, and also a host of observations and opinions gathered from competent physicians living in places where the malady had occurred, together with reports, bearing on the question, from many localities where the disease was unknown, or known only through vague and unsupported tradition.

Two deductions may be drawn from this paper. First, that, since the settlement of the country, intermittent fever, whether as an endemic or an epidemic disease, was almost unknown in Eastern Massachusetts; and second, that the testimony of the greater number of observers was to the effect that the disease is generated spontaneously in swampy situations, and is bred autochthonously in heat, moisture and vegetable decay.

The author in his introduction is at some pains to demonstrate with his inimitable felicity of style and force of diction, that here, in our own New England, are presented all those conditions of latitude, of climate, of rainfall, of summer-temperature, and of soil, supposed to contribute to, if not to cause, the existence of malaria in the pestilential districts of Europe, but leaves "aside all discussion of the more subtle questions which naturally arise."

Dr. Holmes gives a map on which he notes a few places east of the Connecticut river where intermittent fever was believed to have arisen. In most instances the evidence appears hardly sufficient to prove indigenous origin. In the town of Hopkinton, Mass., it seems that in the last century some cases occurred in the vicinity of two ponds; and reference is now made to this fact as a matter of curious interest in connection with the epidemic in Framingham. It is well known that the neighborhood of Providence, R. I., has been repeatedly visited by malaria. Now the Blackstone river, which makes its way to the sea by Pawtucket and Providence, has a source in one of these infected ponds, while the river Sudbury, which flows through Framingham, arises from the other pond, the smaller feeders of the two streams flowing in adjoining meadows.

Another very valuable contribution to this subject is the able and thorough paper published in the Massachusett State Board of Health Report for 1880, written by Dr. J. F. Alleyne Adams, of Pittsfield.

In 1877, '79 and '80, it appears that there were twenty cases of intermittent fever in eastern Massachusetts, eleven of which were in Worcester County, five of them, the largest number in any one town, being in Hardwick, the extreme western boundary of that county. In Middlesex there were four, one in Ayer, one in Woburn, one in Billerica, and one in Wakefield. Three cases are reported from Taunton, in Bristol County, in 1879. None other are known to have occurred since 1836.

But this paper of Dr. Adams is especially interesting, as showing how views had changed with regard to etiology of the disease. Several observers remark the fact that it occurred independently of heat and marsh miasm. In most instances, some reference is made to the acknowledged agency of dams and swamps in its production, while clearly intimating that some other more important factor remains to be discovered.

Within the period covered by these papers, there have been three distinct epidemics of intermittent fever in New England — the first at the close of the last century, the second in 1836–37, and the third in 1879–80. The intervals have varied somewhat, but may be roughly said to be about forty years. In the second outbreak it appeared in places not attacked before, and in the third, again it advanced to new localities. There were, besides, a few places where it was seen in the intervals of these epidemics.

During one space of forty years, we have no record of intermittent fever anywhere in the State of Massachusetts, and for fifteen years, if we except south-west Connecticut, it was not seen in New England.

Dr. William H. Thayer, in a paper on "Malarial Fever on Long Island," (*N. Y. Med. Jour.*, March 7, 1885), says: "Its northern boundary in North America, as an endemic, is apparently regulated by two causes, more or less combined: the character of the soil and the mean temperature." "Eastward of the Alleghany Mountains its northern boundary, as an endemic, coincides with the isothermal line of 70° F. of mean summer temperature, which, beginning about Sag Harbor, L. I., runs west-northwest to the Hudson River about West Point, thence north as far as Watervliet Arsenal, thence south-westerly through Carlisle, Pa." "This places the greater part of Long Island, Westchester County, and the valley of the Hudson as far north as Watervliet, within the boundaries of the endemic, which will be shown to agree with the record."

Outside of these limits, described by Dr. Thayer, is a sort of debatable land, where malaria occasionally appears as an epidemic. Within this latter area, along the Connecticut River, in the valleys of Berkshire and Franklin, and about Long Island Sound and its bays, perhaps as far as Providence, R. I., there are localities where the favorable conditions of soil-moisture and summer temperature combine to make it almost endemic.

Some fifteen years ago, intermittent fever seems to have set out on a hostile march through New England. Beginning in south-western Connecticut, it has moved forward slowly year by year, generally in a north-easterly direction. Its course has been somewhat erratic, usually following up the streams, often doubling upon its track, making wide skips of twenty or twenty-five miles, and then going back again. The column has usually been preceded by a small skirmish line, the main advance not being made until the next year or the year after.[2] In some instances it has first appeared upon high ground, and remote from marshy or wet lands.[3]

Framingham occupies nearly the geographical centre of eastern Massachusetts, and is about 30 miles from Providence, 70 from the Connecticut River, and 100 from New Haven, these being, it is believed, the nearest points where malaria may be said to exist in a quasi-endemic form. The town of Thompson, in north-east Connecticut, is perhaps, topographically, the nearest of any where it has appeared, that in 1881, the nearest as regards time, as well as distance, being Providence, R. I., where it prevailed in 1883–84.

South Framingham is on the Boston and Albany Railroad, and is the point of junction of several important railway lines. The village covers about 600 acres on both sides of the railroad, and contains 4,200 inhabitants, 750 families occupying 500 houses. It is a

[2] This is said to be the case in some of the towns invaded in the State of Connecticut, and in Massachusetts also. Dr. R. W. Griswold, Report of the State Board of Health of Connecticut, 1885. South Framingham seems to furnish an exception to this rule.

[3] This was the case at Rocky Hill, Meriden, and East Lyme, Conn., and in some of the towns in this State.

manufacturing place, and growing rapidly. It lies between the Sudbury River basin and that of Lake Cochituate.

The soil of South Framingham is a sandy loam of little elevation, resting upon an extensive bed of quicksand, which underlies all the adjacent country, and is of varying depth and indefinite extent. This quicksand everywhere contains water, so far as known.

On the south and east of the village lies a wide, swampy region of some 3,000 acres in extent, called Guinea Meadows, constituting the water shed of Beaverdam Brook, a stagnant, obstructed stream which empties into Lake Cochituate. These swamps, which are partly wooded, are composed of a retentive peat, spongy, and in some places, of great depth. Into this bog the sewage of the village filters, or is led by means of ditches and drains. In spite of these unwholesome surroundings, the place is not unhealthy.

The part of South Framingham where the chief force of the epidemic of intermittent fever was felt in the summer of 1885, lies south of the Boston and Albany Railroad.[4] It differs somewhat from the rest of the village in three respects: *First*, it is contiguous to, and partly built upon, the Guinea Meadows. *Second*, it is traversed and bounded on one side by a deep, stagnant ditch, which comes especially under suspicion. This was made by the city of Boston in 1872, in order to connect the Sudbury River with Lake Cochituate by way of Farm Pond and Beaver-dam Brook. It has, however, for many years been abandoned and shut off completely from the pond. It has become stagnant, or nearly so, and its wooden sides have rotted and fallen in. A good deal of drainage runs into it. *Third*, when the wind is north-west, which was frequently the case during the epidemic, it comes directly from an area of about forty acres in Farm Pond, which has been isolated, become stagnant, and is covered with a rank, coarse vegetation.

The district infected contains, roughly, one-third of the area and one-fifth of the population of the main village. It covers about two hundred acres, half of which, perhaps, is swamp and not habitable. Five-sevenths of the houses in this region were attacked, and in some cases, every person in the house.

Among the supposed contributory causes which have existed for a long time in this locality and in various parts of Framingham without the appearance of intermittents, may be mentioned: a high summer temperature, hot days and cool, damp nights, with the peculiar effluvium of swamps and decaying vegetation; dry seasons and low wells; spring freshets choking up the drains of meadows with silt, and leaving stagnant pools "festering and evaporating in a summer's sun;" the digging up of the soil, making new streets, etc.; and the rank growth of vegetation in swamps and hollows. All these things have existed in perfection for an indefinite time in various parts of Framingham during the hot weather.

The connection of malaria with *dams* and artificial reservoirs, especially upon sluggish streams having banks of little elevation, and where wooded swamps are flowed, causing foul exhalations and effluvium when the water is low, is too much insisted upon by observers to be hastily denied. In the thirty towns of Massachusetts visited by epidemics of this disease in the past and present century, there are very few where this condition does not exist. Further, it is an admitted fact that in other countries and in this, and especially in New England and in our own State, that the removal of dams and draining off of reservoirs has coincided with, and is believed to have been a cause of, the disappearance of the pest.

As already said, in 1876–77 the city of Boston, having decided to take the Sudbury River for an additional water-supply, began the erection of three large dams within the town of Framingham.

The Sudbury rises in Hopkinton and Westborough. It is a slow stream, having little fall, and wide margins of meadow and swamp, often wooded. It winds through the town of Framingham from the south-western corner to the northeastern. Stony Brook, a large tributary upon which was placed a high dam, is a quick stream, but is, or was, bordered with wide areas of peat bogs and woods.

The watershed of these streams is largely composed of land which has been, for more than a century perhaps, used for farms and plentifully treated with barnyard manure. The water of both streams has always had a yellow tinge and pondy taste.

In making these dams the streams were turned aside, their beds exposed and deep excavations made, in some places of thirty feet. Great quantities of alluvium and peat were removed in this work, as was also the case in laying the main conduit to Chestnut Hill, which, as it quits Farm Pond, passes directly through the now infected area of South Framingham and crosses the Guinea Meadows. The workmen, numbering many hundreds, lived in barracks or shanties built upon the low ground near the bed of the streams, or in the woods and swamps; and most of the work was done in summer, the water being then at the lowest. They lived in the constant association of meadow-mud and fog, drank the water of the streams and worked in summer heat, and yet not a single case of intermittent fever appeared among them nor in the town anywhere. In 1877–78 the bottom of reservoir No. 1 was dug up from end to end for the purpose of laying a 48-inch connecting pipe.

During 1878–79, the dams being completed, the basins were filled and connection was made with Farm Pond, a natural body of water of no great depth which was utilized as a settling basin. In this manner about 850 acres were occupied by these reservoirs, representing a surface about one-eighth as large as the whole acreage of that portion of the town which from its elevation might presumably receive malarial infection from this source.

At various times since the filling of the reservoirs the water has been drawn off and the bottom exposed, and remained in that condition for months. Hundreds of acres of "drowned lands," covered with black mud and rotting stumps of trees and sending forth a horrible stench, have thus been laid open to the sun. The mud has been removed and placed upon the banks, or used to fill up the dead ends and shallows.

Farm Pond was drawn down in 1881 seven feet, and a temporary channel made around its shores, and in this work great quantities of the muddy bottom were removed.

The smell of sulphuretted hydrogen was, in summer, always perceptible in the sluice-ways and gate-houses at the dams.

In the summer of 1879 the water in the largest basin (No. 3, on Stony Brook) became offensive.

[4] Cases occurred in various parts of the town remote from this region.

This was found to be due to the growth and decay of certain minute algæ, described as follows by Mr. A. Fteley, the resident engineer, in his superb report on "Additional Water-Supply, City of Boston, 1882."

"These minute plants, which appear to be uniformly distributed throughout the water, flow with it, and are of such small bulk that they cannot be separated by screens; the wind has a noticeable effect upon them, and often blows them toward the lee shore, where they accumulate and form a solid scum of a sharp green color. When in the fresh state they emit a very peculiar musty odor: if stranded by the action of the wind they soon decay and form a bluish-green mass, and develop a smell as of organic matter in the process of decomposition. When in the water the algæ remain suspended for some time, and after a while sink to the bottom. Of the formation of the algæ, or of their origin, little is known; but it is remarkable that they appear very suddenly in large quantities, . . . equally distributed through hundreds of millions of gallons of water, twenty feet deep, several hundred feet from any shore, and in very calm weather, . . . increasing or diminishing with wonderful rapidity."

It remains only to add to this admirable description that the sudden disappearance of these organisms was as unaccountable as their appearance, and that the peculiar fœtid effluvium which was caused by them was distinguishable at a long distance from the reservoirs.

In the fall of 1881, the fishy or "cucumber" taste, which has occasionally developed in the Cochituate water-supply, was found in the water of Farm Pond. Professor Ira Remsen, of Baltimore (see his report on the impurity of the water-supply, City Document, No. 143, 1881), attributed the objectionable taste to the presence of a "species of fresh-water sponge, which was found in small quantities on the gravelly or stony parts of the bottom of the pond." "After a short time the bad taste in the water disappeared."

At this time there was an offensive and peculiar odor in the neighborhood of the pond.

The object of these details is to show that at various times during a period of eight or nine years previous to 1885, all those conditions which, in connection with the building of dams and formation of artificial reservoirs, are cited as being *contributory* causes at least of malaria, had been in operation in Framingham without producing intermittent fever.

It is only necessary to say further that the point where the epidemic of 1885 raged with greatest intensity is more than a mile from the nearest basin, and a mile and a half from any of the dams. No cases in fact occurred about the dams, and very few in the neighborhood of the reservoirs. It is true Farm Pond lies contiguous to the locality; but this is a natural body of water, although receiving that of the basins above.

The history of the epidemic requires but few words. It is hardly necessary to say that intermittent fever, at least in its epidemic form, can scarcely be mistaken for any other disease. A few scattered cases were seen in June and July. The latter month was hot and unusually dry. At the close of July there was a change of weather and a heavy fall of rain. This was immediately followed by the appearance of many cases. August was cold, colder than for fifteen years, and the amount of rainfall was very great (more than seven inches), much greater than had occurred for a long series of years, August being generally hot and rather dry. Between the end of July and the latter part of September, when the disease began to decline, more than 200 cases were seen and reported by the various physicians of the town. Others are believed to have occurred which were not seen and not reported.

As usual the type of the disease was tertian, rarely quotidian, more rarely still quartan. In many cases there was but one severe chill. People of all ages were attacked. There was generally a day or two of malaise or headache before the seizure. Vomiting was a frequent occurrence. The chill lasted one, two or more hours; the fever was intense, and was followed by profuse sweating, which continued in many cases far into the night. On the following day the patient was found completely recovered, or complaining only of weakness. There was one death, a feeble woman and very old, who refused all treatment. An Italian, one of the workmen upon the new conduit in Farm Pond, was sent to some State Institutton, where he is reported to have died from the fever. During the epidemic two cases of severe typhoid fever were seen by the writer in consultation in South Framingham.

Quinine was given in most of the cases, and with the usual success. Recurrent attacks, prolonged anæmia, enlarged spleens, and the other sequelæ were observed; but by far the greater number of patients recovered completely after a longer or shorter time.

As to the mode of introduction, the avenue by which malaria enters any locality, little can be said that is not more or less conjectural. The vehicle is probably water; but whether it descends in the form of rain or dew, or rises from the ground, or is drawn from springs or wells, we have no positive evidence to decide. It was remarked in the present instance that a large number of cases developed on the days succeeding two quite copious falls of rain. If this is the method of entrance, it may explain the apparent anomaly of the first appearance of malaria upon ground where no standing-water is seen.

But the source of the water which flows in the subsoil, or in the crevices of the strata of rocks, is something of which we know very little. "Barometric springs," as they are called, are found in New England, which in dry seasons suddenly burst forth, it is said, and flow in full volume many hours before the actual appearance of rain in their vicinity. Whence comes the vast body of water in the extensive wet quicksands underlying some parts of the county of Middlesex? It is believed by many that this water has a flow. Competent authorities maintain that malaria enters the body in the drinking-water. If this is the case, a distant source of the springs that feed the wells may explain the appearance of malaria in a spot where neither of the so-called factors, namely, heat, soil-moisture and vegetable decay, can be shown to exist.

(To be continued.)

— In May, 1883, obligatory vaccination was abolished in Zurich. In 1882 there were no deaths from small-pox. In the first three-quarters of 1883 none. In the fourth quarter the deaths from small-pox were eight in a 1,000 of total deaths. In 1884 in a thousand deaths there were from small-pox, the first quarter, nine, second, none, third, none, the fourth two and one-half. In 1885 in the first quarter six, second, fourteen, third, fourteen, fourth, thirty-eight. In 1886, first quarter, eighty-five.

REPORT ON PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

TREPHINING IN CASES OF HÆMORRHAGE FROM THE MIDDLE MENINGEAL ARTERY, WHERE THE SKULL OR SOFT PARTS ARE UNINJURED.

In the past three years, Krönlein [1] has opened the cranial cavity for hæmorrhage from the middle meningeal artery and resulting hæmatoma in four cases where neither wound of the skin, nor fracture of the skull existed.

The diagnosis was correctly made in every case. In each instance there was found a marked supra-dural extravasation in the region of the arteria meningea media. Two patients recovered. Cerebral hæmatoma may be (a) diffuse, or (b) circumscribed. Of the latter (b), Krönlein makes the following classification, according to the seat of hæmorrhage:

First. Hæmatoma media, or tempero-parietale, of the middle cerebral fossa (a region supplied by the trunk and anterior or posterior division of the arteria meningia media) due to hæmorrhage from the anterior branch of the anterior division.

Second. Hæmatoma posterius, or parieto-occipitale — parietal eminence — due to hæmorrhage from rupture of the posterior branch.

Third. Hæmatoma anterius, or fronto-parietale — frontal eminence.

The tempero-parietal region is the most common seat of injury (a) from the vulnerability of the region, (b) from the size and number of vessels, it being the seat of the trunk and the main branches. All hæmatoma are accessible at the anterior inferior angle of the parietal bone, with the exception of the circumscribed ones of the parieto-occipital region. If the hæmatoma is not found here, the parieto-occipital region must be explored, and the point for trephining is under the parietal eminence. Krönlein's indications for surgical interference are symptoms of cerebral compression, and his rule for locating the points for operation are as follows:

(1) A line called the horizontal line of the skull, namely, one passing from the infra-orbital border to the external auditory meatus.

(2) A horizontal line parallel with the above, and projected backward from the supra-orbital ridge. Both points of operation are in this line.

(a) The anterior; three to four cm. posterior to the zygomatic (ext. angular) process of the frontal bone.

(b) The posterior; at the point of intersection of the above horizontal lines, and one projected vertically, from a point just posterior to the mastoid process.

Krönlein claims that a double operation is indicated not only in cases where a single perforation fails to find the seat of extravasation, but also in cases of diffuse hæmatoma, since the clot can be more completely removed, and also a better opportunity afforded for drainage, should such be necessary.

CONTROLLING BLEEDING DURING EXCISION OF THE TONGUE.

Mr. Jordan Lloyd [2] describes a method of controlling bleeding from the tongue during partial or complete excision. The patient is placed under ether, a gag adjusted, the left index finger is carried well to the bottom of the glosso-epiglottidean pouch, defining clearly the hyoid bone with its cornua, the front of the epiglottis, and the back of the root of the tongue. A stout, long, well-curved, mounted needle, threaded with medium-sized whipcord, is entered from the front of the neck, in the middle line, immediately above the hyoid bone; one feels for the point of the needle with the left finger, as the instrument is pushed through the root of the tongue. In this way, the epiglottis is protected from injury, and nothing more than the lingual tissues are transfixed, then hook up the loop of thread with the left finger, and pull it well through and out of the mouth. Withdraw the needle, liberate the thread from it, and cut through the loop. Now enter the empty needle at the same point of puncture, through the skin only, and pass it subcutaneously to the right, until its point is opposite the upper border of the root of the great cornu. Care must be taken to keep just under the skin, and so avoid the lingual artery. Now turn the point inwards above the great cornu, so as to enter the bottom of the side of the pouch, and feel for the point of the needle with the finger. Thread one of the ends of the cord, which is in the mouth, through the needle, and withdraw. This casts a loop around the right half of the tongue. The left half may be dealt with in a similar manner.

TREATMENT OF AORTIC ANEURISMS BY THE INSERTION OF WIRE.

Ransohoff [3] reports a case treated by the introduction of ninety-six inches of silver wire into a sacculated aneurism of the ascending aorta; the result was temporary improvement, followed by death in a month from the time of operation. There have been fourteen cases reported in which this method of treatment has been applied, all terminating fatally, except in Stimson's case, where the result was negative.

Dr. Ransohoff thinks that there are ample reasons for repeating the operation in suitable cases. In the first place, death has in no instance ensued during the operation, although the possibility of such an occurrence is conceded. In four cases, death followed on or before the fifth day after the operation, so that in only thirty per cent. of the cases can death be attributed to the operation itself, while in the remainder it is in no way dependent upon it. The post-mortem reports show that coagulation almost invariably took place in the sac; the clot was found laminated and often adherent to the sac wall. Life was sustained for periods varying from three weeks to as many months from the date of operation. It should never be resorted to in aneurisms of peripheral vessels when so many safer methods are at command; nor is it admissible in internal aneurisms until all ordinary therapeutic measures have been fairly tried. Practically, as a last resort in such cases, it has undoubtedly lengthened life, and it is far from improbable that, if often adopted, a permanent recovery will occasionally be obtained in cases that are hopeless without it. The subject of the treatment of aneurisms by the introduction of filiform material was discussed at the Royal Medico-Chirurgical Society.[4] The general opinion seemed to be that such a measure must be regarded as a last resort. Mr. Holmes was in favor of the employment of a less rigid material than wire, instancing catgut and horse-hair, of which he thought the latter the better.

MODE OF FRACTURE OF THE FIRST RIB ALONE.

The mechanism of this injury is considered by W. Arbuthnot Lane.[5] He considers that it may be fractured by force applied directly to the seat of fracture when this is in the posterior portion of the rib. The direct force required to break the first rib at this point must of necessity be great, and would probably also fracture the scapula. It may be broken by force applied to the manubrium. This is a more probable means than the first, as the first rib and cartilage are closely connected to this bone. However, on account of the great obliquity of the first costal arch, force applied to the manubrium would be much more likely to produce fracture or dislocation of the sternum than fracture of the first rib or cartilage alone. The most likely way Mr. Lane considers to be that the first rib is broken by force transmitted to it through the clavicle. In a paper,[6] "One Mode of Fracture of the Sternum," he showed the immense leverage exerted by the clavicle on the anterior portion of the first rib when force is applied in a vertical direction to the shoulder or outer end of the clavicle. Mr. Lane considers that he proved that the force so transmitted by the clavicle tended to fracture of itself (probably the common result), the rib, the first costal cartilages, one or both, and to fracture or dislocate the sternum at the junction of the manubrium and gladiolus; in fact, to break the costal arch, which consists of the first two ribs with their cartilages and the manubrium, or tear it away from the gladiolus.

LAPAROTOMY IN THE TREATMENT OF PENETRATING WOUNDS AND VISCERAL INJURIES OF THE ABDOMEN.

Rarely do we come across a more practical paper than that contributed by F. S. Dennis,[7] on the above subject. The paper and discussion deserves careful attention from every surgeon and we append some of the conclusions. Dr. Dennis considers that penetrating stab wounds of the abdomen are less fatal than penetrating gunshot wounds. That if the stab wound has injured the intestines or any abdominal organ or if any doubt exists, laparotomy is indicated. Laparotomy offers no great additional danger to the patient if properly performed under the strictest antiseptic precautions. The enlargement of the original wound for an examination of the peritoneal cavity will not enable the surgeon to exclude in all cases fæcal extravasation, perforation, volvulus or hæmorrhage. The size, shape, character and velocity of the bullet, the attitude of the patient, the kind of weapon used to produce a stab wound, seem to influence the question of laparotomy.

If there is any value in abdominal section, it should be promptly performed, irrespective of the facts connected with the penetrating abdominal wound. Fatal hæmorrhage from the large venous trunks in the abdomen may occur, and this hæmorrhage not be discovered until the peritoneal cavity is about to be closed. The sutures, if properly applied, will close the perforation in every case, no matter how lacerated these wounds are. The sutures will close the wound in case of resection of the gut, so that no leakage will occur if water is forced through the sutured intestine. The success of laparotomy is to be attained where every arrangement is complete and perfect. Everything depends upon the preparation which is made for this operation, and the antiseptic conditions under which it is performed. Shock, perforations, and the resections of injured parts of the canal, are all important steps in this operation.

Dr. Dennis further believes that in the present unsettled state of opinion, it would seem best not to perform this operation in medico-legal cases without the full sanction and support of a consultation.

DANGER OF GANGRENE TO THE INTESTINE INCURRED BY SEPARATION FROM ITS MESENTERY.

D. G. Zesas,[8] in an interesting article, has published the results of his experiments (on this subject), with a brief *résumé* of the most recent investigations. His observations show that the vitality of the intestine is dependent upon the integrity of the vascular system at its mesenteric attachment. This cannot be injured without great danger of gangrene resulting from interruption of nutrition. Separation, on the other hand, of the mesentery not less distant than two to three cm. is comparatively harmless, since the abundant anastonosis distally situated protect the intestine from interference of nutrition without difficulty. His conclusions are:

(1) That portion of intestine must always be resected which has been separated from its mesentery at its point of attachment to the gut, for gangrene is inevitable.

(2) Resection is not necessary (of the separated tract) when the point of separation is two to three cm. distant from the intestinal attachment.

(3) The greater the extent to which the intestine is separated the greater the danger of gangrene.

(4) In transverse sections of the intestine the mesenteric separation should be avoided beyond the line of division; or danger of gangrene occurs.

(5) Small and large intestine tolerate equally well a distant separation from their mesenteria.

EXTIRPATION OF RECTUM FOR HIGH-SEATED CARCINOMA.

Ordinarily cases of carcinoma of the rectum whose upper border cannot be reached by examination per anum, and in which infiltration has fixed the adjacent tissues are considered beyond surgical interference.

The limited field of operation available to the surgeon even after removal of the coccyx, has caused the removal of these tumors to be exceedingly difficult and uncertain. Kraske[9] has attempted to enlarge the field of operation by a partial excision of the sacrum. After preliminary dissection on the cadaver to demonstrate the practicability of his proposed operation he extirpated the rectum in the living subject successfully in the following manner: With the patient lying on the right side an incision is made in the median line from the centre of the sacrum to the posterior border of the anus, through the soft parts to the bone. The left gluteus muscle is dissected from its insertion to the lower portion of the lateral border of the sacrum — the coccyx is excised; then the exposed greater sacro-sciatic ligament (tuberoso-sacrum) and the underlying lesser ligament (spinosa-sacrum) close to their attachment to the sacrum are divided. The edges of the incision are separated by retractors. The left border of the sacrum is then chiseled away

along a curved line (concavity to the left) commencing at a point on a level with the third posterior sacral foramen passing through the lower border of the same foramen and continued downwards and inwards to the left inferior sacral cornu. No regard is paid to the posterior division of the sacral nerves. The anterior division of the fourth and fifth nerves are divided but not of the third. After the remaining soft parts covering that portion of the rectum thus exposed are divided, the patient is placed in the lithotomy position with pelvis well elevated. The lower end of the rectum divided at the anus or at the lower border of the disease — the sphincter is often saved — the intestine can be isolated to the sigmoid flexure with considerable ease and accuracy. Of the structures involved the insertion of the glutæuo — the sacro-sciatic ligaments — the posterior branches of the third, fourth or fifth sacral nerve, result in no essential disturbance of function. The anterior branch of the third sacral, which is an important part of the sacral plexus is not injured, nor is the sacral canal opened.

The peritoneal cavity if opened by high section of the rectum is closed by suturing. The wound is packed with iodoform gauze after draining the peritoneal cavity.

TREATMENT OF THE PERITYPHILITIC ABSCESS.

In a paper contributed to the Practitioner's Society of New York [10] Dr. W. T. Bull calls attention to the vital necessity of an early needle exploration of perityphilitic abscesses followed by the immediate evacuation of pus. The question in these cases is to determine when pus has formed. Dr. Bull records a case in which a perityphilitic abscess was opened forty-eight hours after the symptoms became acute and the patient took to bed. He considers that the thorough exploration with the needle and hypodermic syringe is imperative in these cases. He uses a good sized needle (No. 3 or 4 of the French scale of urethral instruments) and a "tight" syringe. He considers the punctures harmless; and, not only would he aspirate in the iliac fossa but considers that one should also puncture through the lumbar region, with the needle, passing it downward and forward towards the middle of the iliac fossa, when punctures directly into the fossa or the tumor occupying it are fruitless.

Dr. John Homans [11] reports a case in which he operated upon a perityphilitic abscess within forty-eight hours of the doctor's first visit. He could not find a dull place in which to pass a needle and so dissected down through the locality. If he had passed a needle in he would have perforated the bowel four times before the needle would have reached pus. The patient recovered. From these recorded cases, early exploration of acute perityphilitis becomes imperative to the surgeon.

NEPHRECTOMY.

Samuel W. Gross in a paper considering the "Indications and Contra-Indications" for this operation [12] has made a valuable addition to this interesting subject. Of two hundred and thirty-three cases of extirpation of the kidney which he has collected he finds a mortality of 44.63 per cent. Of the entire number, two hundred and thirty-three, one hundred and eleven by the lumbar incision indicate a mortality of 36.93 per cent., while of one hundred and twenty by the ventral incision 50.83 per cent., died. This makes the fatality of the abdominal operation greater by 13.90 per cent. than that of the lumbar operation.

Dr. Gross after carefully analyzing the facts that he has collected, feels justified in formulating the following propositions:

First. That lumbar nephrectomy is a safer operation than abdominal nephrectomy.

Second. That primary extirpation of the kidney is indicated, first, in sarcoma in adult subjects, secondly, in benign neoplasms at any age; thirdly, in the early stage of tubercular disease; fourthly, in rupture of the ureter; and, lastly, in ureteral fistula.

Third. That nephrectomy should not be resorted to until after the failure of other measures, first, in subcutaneous lacerations of the kidney; secondly, in protrusions of the kidney through a wound in the loin; thirdly, in recent wounds of the kidney or of the ureter, inflicted in the performance of ovariotomy, hysterectomy, or other operations; fourthly, in suppurative lesions; fifthly, in hydronephrosis and cysts; sixthly, in calculus of an otherwise healthy kidney; and, finally, in painful floating kidney.

Fourth. That nephrectomy is absolutely contra-indicated, first, in sarcoma of children; secondly, in sarcoma at any age, unless, perhaps, the disease can be diagnosticated and removed at an early stage; and, thirdly, in the advanced period of tubercular disease.

Le Dentu [13] considers the operation to be contra-indicated in the following cases:

(1) Sarcoma in children.
(2) Carcinoma except in cases of early diagnosis.
(3) Advanced tuberculosis.
(4) Other affections. Pyo and hydronephrosis. Also ren mobilis which has resisted all other therapeutic attempts.

He describes two operations.

(1) Extra peritoneal.
(2) Intra (or more properly named) trans peritoneal. This has a very limited field only, and is to be performed in cases of wandering kidney with a thin pedicle and of large hydronephrosis or neoplasms which project far between the peritoneal folds. But in such cases it is doubtful if any operation would be justifiable. In describing the operation the full details are of value.

I. EXTRA PERITONEAL OPERATION.

The position recommended for the patient as most satisfactory is one half between prone and lateral decubitus resting on a firm pillow placed between the thorax and pelvis so as to give as large a field for operation as possible. It is also most favorable for forcing the tumor into the wound if required.

The use of the thermo-cautery to control hæmorrhage is discountenanced. It is claimed to interfere with a rapid recovery, and is inefficient to stop hæmorrhage except that from small vessels.

Incision. Is varied with each case but in general one vertically downwards from the eleventh to twelfth rib to the iliac crest is recommended. This can be prolonged backward at its superior end or forward at its inferior, if a larger incision is required. (Czerny, Clement Lucas). The tip of the twelfth rib is the only portion of the thoracic border which can be resected without danger of injury to the pleura.

Enucleation. When the capsule is found adherent to important structures or organs, it is incised along the greater curvature of the kidney and the organ enucleated through the incision.

Pedicle. Is best ligated *en masse* with silk or catgut ligatures, which can be reinforced with an elastic ligature if necessary. By temporarily securing the pedicle with a clamp the tumor can be removed and a convenient space obtained to permanently ligate it.

Treatment of the wound. If the extirpation has been complete the wound can be drained and closed. When the removal has been partial it is advised to pack the wound with antiseptic gauze and to allow it to close by granulation.

The emergencies which can occur are:

Wounds of the pleuro-peritoneum or intestines. These should be sutured at once.

Hæmorrhage. If the bleeding vessel cannot be seen the pedicle should be secured as rapidly as possible. Parenchymatous bleeding is rare and controlled by packing.

II. INTRAPERITONEAL OPERATION.

Incision. ("Langenbuch's"). At the outer border of the corresponding rectus muscle. The incision of the posterior layer of peritoneum is made externally to the mesocolon.

Pedicle. Is to be ligated previous to enucleation to diminish the danger of hæmorrhage.

Treatment of the wound. The cavity resulting from the operation should be drained posteriorly through a lumbar incision and the wound of the peritoneum then closed.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY. SUFFOLK DISTRICT. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.[1]

ALBERT N. BLODGETT, M.D., SECRETARY.

Dr. H. C. Haven read a lengthy and elaborate paper on

THE ETIOLOGY AND TREATMENT OF SUMMER DIARRHŒA OF INFANTS.

Dr. Buckingham said that the paper of Dr. Haven is a hard one to discuss without having it before one, because it deals largely with statistics. He agreed with it, that in estimating the value of children's foods, great consideration should be paid to other factors, and that a child with good hygienic surroundings and comparatively poor food, will often thrive more than another child with better food but poorer surroundings. He was glad that Dr. Haven had emphasized this fact because it is so often ignored by writers on the subject.

It is certainly rational as is stated by the writer, when constructing an artificial food, to copy as nearly as may be the natural food of the child. He was unable, however, to agree with Dr. Haven, if he had understood him rightly, that the food need not vary in strength with the age of the child; for although it may be true that the mother's milk does not vary from month to month, a matter about which he expressed no opinion, yet he believed it to be a clinical fact that many children do not digest so undiluted a food at birth, as they can a few months later, even of a kind on which they do reasonably well when it is diluted. He furthermore disagreed with the reader as to the clot being of no importance.

The speaker had had no experience with some of the foods studied by Dr. Haven, but had for some years used mostly a mixture of milk and cream, sweetened, made alkaline and more or less diluted. This he had used both in private practice and elsewhere; largely in the children's room of the Boston Dispensary, and with increasing confidence. The objection to cream on the ground of expense and of its greater age, he had obviated by having the milk stand a half hour or an hour, and then pouring from the top as much as may be wanted for the day's use. Of course the value of this course depends on a certain reliability on the part of the milkman: but the method, which is not original with him, does often give practical results, even when used in dispensary practice in this city. The suggestion of the reader that the salts in milk play an important part may prove true. It is certainly rational to suppose so. Practically he had himself used the alkaline bicarbonates for making milk alkaline; but had changed to lime-water, at first in dispensary practice, on account of its greater convenience, and afterward in private practice, using half as much lime-water as milk, and further diluting with water if he thought proper. He had not seen any difference in the result.

It is interesting to observe that Dr. Haven got no starch reaction in the fæces of babies into whose food barley water entered, thus bearing out the statements of physiologists that the parotid has commonly, though not always, a diastatic power at birth. When we remember the further results of the laboratory, that the pancreas has no such power for two or three months, although to this rule also, there are exceptions, we can understand that the reader's results are in no way incompatible with the common clinical experience that where starch enters largely into babies' food, the result is often disastrous. The reader's statement that barley contains in itself some diastatic power was of interest.

Dr. Bennett F. Davenport spoke of the

PHYSICAL AND CHEMICAL QUALITIES OF ORDINARY COWS' MILK,

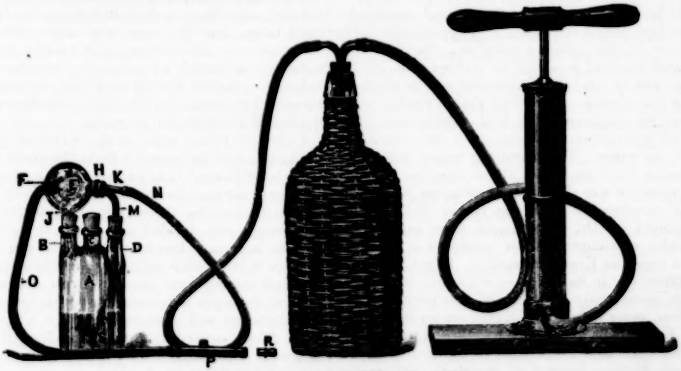
and added: The question of the age of the milk which is given to our city children, I consider as of very much greater importance than it is usually deemed by physicians. There is no fluid that I know of which is a more rapid absorbent of foul odors of all kinds, or which offers a more fertile field for bacterial growths. Yet most of the milk, even when just delivered to the consumers in this city is already in its third day of age, and has been exposed to a probability of contamination so great that I very much wonder that it does not become downright soured before the time of the next daily delivery. Very much of it is but very little short of this stage. I am firmly persuaded that it is to this changed condition in the milk, to which city folks have become so accustomed, as to consider it the proper and natural condition, that a very large proportion of the summer diarrhœa, and the resulting mortality among the children in our cities is due. If

[1] Concluded from page 31.

any one wants ocular proof of the grosser forms of contamination to which city milk is exposed, he has but to visit any of the larger milk depots of the city, and to look at the nature and the quantity of the foreign material left upon the cloth strainers connected with the centrifugal machines used for separating the cream from the surplus milk of the day. If he does not then learn by seeing with his own eyes what he could otherwise hardly be brought to believe to be possible, I am very much mistaken as to what are the real facts. Very fortunate indeed, would it be if only the firm and already dissolved impurities could also be thus readily separated out from the milk.

We, as physicians, have learned to know that milk about upon the point of changing will more disturb the digestion of a child than that which has already turned sour. I believe that the difference in the coagulation of breast and cow's milk in a child's stomach is more owing to the difference in the chemical reaction of these two milks, and in the amount of albuminoids contained therein, rather than to any difference in the nature of these albuminoids, for cow's milk, even when fresh, is of an acid reaction, while breast milk is neutral, or may be slightly alkaline. Then, too, cow's milk contains a much larger amount of albuminoids. Making cow's milk of a neutral or slightly alkaline reaction will render this curd finer and softer, and this is also accomplished by diluting with fluids or with soft solids, for which barley flour or malted extract serves well.

When it is desired to add cream to the diluted and sweetened milk when prepared for a child, I think it is better here in the city to use sweet cream raised by the centrifugal machine, rather than that obtained by separation from standing, which necessitates it being just so much the older, when one of the chief troubles is that it is already too old. Such sweet cream is to be had at the large milk depots in the city.



I think that if physicians would instruct all their patients to demand that their milk be delivered to them the same day that it is brought into the city from the country, that this would become the more common custom of the trade, and that there would be a marked decrease in the infant mortality during the summer months, for if we cannot secure proper cleanliness in the care of the milk we might at least thus shorten materially the time during which fermentative contaminations would have a chance to work out their harmful changes.

Dr. George W. Galvin exhibited an

IMPROVED INHALER,

which he describes as follows:

The inhaler is the invention of Dr. Geo. A. Evans,

LEACH & GREENE, 165 TREMONT ST., BOSTON.

of Brooklyn, New York, and a full description of it, with a group of cases treated by him, was published in the *New York Medical Journal*, March 6, 1886. The great obstacle to overcome in the local treatment of pulmonary diseases, is the condensation of the vaporized medicament, in the mouth, pharynx and upper air passages. This has been overcome by Dr. Evans' instrument, which can reduce any fluid medicine, or solution to so fine a degree that it can pass the bronchial tubes without condensing and reach the air cells of the lungs in which is stored the residual air. The changes in the lungs in pulmonary phthisis bring consolidation, tissue necrosis, putrefaction, decomposition, and septic absorption (I am not now considering tubercle, its nature, etc., but what is considered pulmonary consumption), it is natural to suppose that if we can convey to the lung an antiseptic vapor which will reach the part undergoing the pathological changes we should obtain practical results from the local treatment of pulmonary affections.

The apparatus consists of an air condensor, an air chamber (flask) for preserving a continuous current of air, a three-mouthed bottle, "Wolf's;" a spray chamber having three mouths, spray tubes; respiratory tube; mouth-piece.

A spray of the solution in the bottle is thrown (by means of compressed air), against the opposite wall with sufficient force to produce a thorough churning with the atmospheric air, a fine vapor, resembling cigar smoke, which escapes through one of the openings in the glass air-chamber to the respiratory tube.

During inspiration through the mouth-piece, air enters the middle mouth of the bottle and displaces the vapor of which the bottle is full. During expiration the air in its turn is displaced passing out of the middle mouth of the bottle, to make room for the

vapor which passes from the glass-air chamber to the bottle, where it accumulates for the next inhalation.

A vapor produced by means of this apparatus condenses slowly, 50 cu. in. of a vaporized solution, containing carbolic acid, borax, glycerine and water, requiring twenty minutes at a temperature of 60° F. to entirely condense.

Ten cases now reported in this JOURNAL with a cessation of symptoms which leads the patients to consider themselves cured, one case of my own far advanced in the second stage of chronic catarrhal pneumonia, after ten inhalations has gained in ten days two and one-half pounds and to all intents and purposes is making a rapid recovery.

DR. W. EVERETT SMITH then exhibited a Semple's Atomizing Inhaler which he has been using in connection with Williams' Pneumatic Cabinet. This inhaler was devised by Wm. F. Semple, of Mount Vernon, Ohio, in August, 1881, and consists of a glass receptacle containing an ordinary atomizer. The medicament is held in the bottom of the jar and is atomized either by a rubber hand bulb or more effectually by a cylinder of compressed air. The spray is projected against the top of the jar, the larger particles are condensed to be re-atomized and only the very finest portions of the spray escape through the inhaling tube.

The vapor thus inhaled has been so churned as it were and broken up that it is as fine and impalpable as smoke and indeed resembles it in appearance. The mouthpiece to the inhaling tube can readily be removed and attached to a flexible rubber tube so that the vapor can be conducted wherever and in whatever direction one pleases. Any fluid that is readily atomized may be employed, the best menstruum being either fluid petrolatum or a twenty per cent. solution of glycerine in water. The resulting vapor will resist condensation for from five to fifteen minutes.

This atomizer was shown to be identical in its principles of construction with the Evans' Inhaler that was exhibited by Dr. Galvin, and when attached to the cylinder of compressed air produced as fine and perfect a vapor as Evans' apparatus. It has, however, these differences in its favor — is simpler in its construction, more easily cleaned and was perfected and in use *four years* before Dr. Evans set up his claim; yet Dr. Evans calls his atomizer a "*new* instrument."

Further than this, Dr. Evans in his article in the *New York Medical Journal* of March 6, 1886, makes no mention of and gives no credit either to the Semple Inhaler or to the Globe Inhaler of Besceer.

Dr. Evans' apparatus is faulty in two particulars; the inhaling tube is long and is complicated with three glass globes which must be kept thoroughly antiseptic if we are to assign any dangerous activity to the numerous germs of disease. The patient under treatment must moreover inhale and likewise exhale through this one tube, the three glass globes and the Wolff bottle which contains the medication; each patient ought therefore to have an entire atomizer reserved for his own particular use, since it would be practically impossible to cleanse *thoroughly* all this complicated arrangement after each application.

Dr. Evans claims, however, as an advantage in favor of his apparatus that the vapor will resist condensation for twenty minutes. But it is easily demonstrated that with any form of atomizer constructed upon these principles, the increase in the resistance to condensation depends *directly* upon the increase in the specific gravity of the fluid atomized and not upon the particular *shape* of the atomizer.

The very fact, however, that the vapor refuses to condense for so long a period as twenty minutes is an objection rather than an advantage to the method of treatment. Everyone grants that ordinary atomizers are of little benefit in the treatment of lung diseases, because the vapor from them condenses almost entirely upon the mouth and pharynx. At the same time no physician would demand that a patient suffering from pulmonary phthisis should actively inhale a medicated vapor longer than twenty or twenty-five minutes at any one time because of the physical exhaustion that would follow a longer treatment. If then the vapor that is inhaled resists condensation for so long a period as twenty minutes, Dr. Smith claimed that it is *just beginning* to be deposited upon the bronchial tubes when the treatment is stopped. He had been better satisfied with the results obtained by a vapor that did not resist condensation for nearly so long a period as that claimed by Dr. Evans.

At the same time Dr. Smith claimed it to be a fallacy that by the use of either the Semple or the Evans' Inhaler atomized vapor can be deposited upon *lung cells*, especially if these lung cells are diseased so that they are unable to be readily expanded. The vapor when finally churned in these inhalers may be deposited and very likely is deposited upon the larger bronchial tubes, but we must remember that bronchial tubes are very different from air vesicles and that the volume of air which we ordinarily breathe — the *tidal* volume — reaches *directly* only the trachea and large bronchi, but enters the air cells in obedience simply to the law of the diffusion of gases.

Unless therefore some of the external pressure of the atmosphere be removed from the chest walls, as it is in the Williams' Cabinet, so that the *complemental* volume of air can be inhaled *involuntarily* into even remote air vesicles, the only medication that can effectually reach any decided area of lung cells must be gaseous in form. But however finely you may divide aqueous vapor under ordinary conditions of temperature and atmospheric pressure, you cannot make it gaseous, for a gas is not condensed except under enormous pressure and at exceedingly low temperatures.

Dr. Smith accordingly, while praising the inhalers that were exhibited, maintained that to derive their greatest benefit they should be used in conjunction with some form of the Pneumatic Cabinet. He has used the inhaler with the cabinet since last December, and has found the results to be highly satisfactory and encouraging.

DR. BOWDITCH said that one of the important objects of any inhaler was to force the substance to be inhaled into the pulmonary structures as much as possible. Whatever the arrangement for inhalation may be, the object to be attained is the pulverization of the substance, and its forcible propulsion into the lungs. The inhaler shown by Dr. Smith is always employed in conjunction with the Pneumatic Cabinet, as an aid to its introduction or propulsion into the deeper parts of the pulmonary recesses.

DR. KNIGHT stated that the instrument exhibited by Dr. Galvin was capable of producing a finely pulverized fluid, and he had never seen anything so fully answering this demand as the one shown at this meeting.

Dr. George B. Shattuck rose and stated that he desired to warn the Section against a travelling individual calling himself Dr. Watson, who pretends to have been shipwrecked on the steamer "Oregon," and who has made appeals for aid to several of the members of the profession here. The man may be a physician, but if so he is a dishonest one, as he had received a contribution of $2.00 from Dr. Shattuck, which had been made to read $5.00 when the list reached other members of the Society.

REPORT ON WATER-SUPPLY.

Dr. Shattuck then presented the following report for the Committee of the Section appointed to consider the present condition of the water supply of the City.

Mr. Chairman:— Your Committee appointed at the meeting of this Society held June 9th, 1885, to co-operate with a similar committee from the Norfolk District Medical Society, which was appointed to take into early consideration the impurities of the Boston water-supply, and to urge upon the mayor the vital importance of promptly using all those means which the law allows to prevent further contamination of that water-supply and to remedy the contamination which exists, beg to report as follows:

Of the five gentlemen appointed upon this committee, owing to absence from town and other impediments, only the two who sign this report were actually able to serve and they did so at some little sacrifice of time and personal convenience.

On June 18th, 1885, in company with three members of the committee appointed by the Norfolk District Society, we visited the Mystic Valley, getting out of the train at Winchester, driving through Winchester and Woburn, and inspecting the tributaries to the Mystic supply and some of the principal tanneries and other industrial establishments upon their banks. The upper Mystic Pond itself was not visited, but the distance from the Winchester station, where the nearest point of pollution observed was situated, to the pond being scarcely half a mile, the possible danger of the situation was sufficiently revealed.

On the afternoon of June 22d, the same members of the two committees made a personal inspection of a portion of the watershed of the Farm Pond and Lake Cochituate water-supply.

The results of these visits of inspection were communicated to the mayor of Boston by the secretary of the joint committee, Dr. E. P. Gerry, of Jamaica Plain, under dates of August 27th and September 5th. The first of these communications, detailing the visit to the watershed of the Mystic supply, was written by Dr. Gerry himself; and the first part of the second communication, giving the results of our observations on the Cochituate watershed, was written by Dr. A. H. Nichols; the latter part of the second communication was added by the secretary and must not be accepted otherwise than as possibly expressing personal opinions of individual members of the committee, certainly not as having an official character. Both of these communications were referred by the mayor to the Boston Water Board, and appeared with some inaccuracies in the daily papers; copies are herewith appended. It is only necessary for us to say further in regard to them that, apart from some comparatively unimportant mistakes as to the names of certain manufacturing establishments, these reports contain a correct, though possibly in some instances (in that on the Mystic) rather picturesque statements of the conditions encountered by us in the Mystic and Cochituate watersheds at the time of our visit.

It is one thing to select and point out sources of pollution of water-supplies, it is another and sometimes much more difficult one to remedy them. Prior to 1884, when complaints were made against public or private corporations or individuals for violations of the provisions of Section ninety-six of Chapter eighty of the Public Statutes, a section designed to protect water-supplies, such complaints were referred to boards of health and local sheriff's juries, with results as you may imagine, going far to render nugatory the provisions of this section. In 1884, owing largely to the efforts of the city of Boston, the Legislature amended the statute so that the Supreme Judicial or Superior Court might in term time or vacation, upon the application of the mayor of a city or the selectmen of a town interested, grant an injunction against any violation of the provisions of the above-mentioned section. At the same time these questions were removed from the jurisdiction of boards of health and of sheriff's juries. Under this amendment a permanent injunction was finally obtained, in March, 1885, from the Supreme Court by the city of Boston, against one Gleason, an inn-keeper, emptying the refuse of his establisment into Pegan Brook.

We desire to say that we believe that the Boston Water Board, strengthened by this action of the Court, has, through its efficient superintendent of the Western Division of the city's water-supplies, strenuously exerted itself to abate the then and the still existing causes of pollution in the Cochituate basin.

Some of these causes can only be satisfactorily removed by the establishment of some suitable systems of sewage-disposal for the towns lying in that watershed. Suggestions for such systems may be found in the late report of the Massachusetts Drainage Commission, which if adopted would probably reduce to a minimum the evils observed by your committee. The sewerage of the Woman's Prison at Sherburne should not be allowed to remain in its present state.

The excavation of the basins of the Sudbury River System puts them in a position where the resources of nature will in all probability not be overtaxed in protecting the purity of the water therein stored. The construction of basin No. 4, which will add 5,000,000 gallons to the storage capacity of this system, has been proceeded with on the most approved modern principles for such work.

To return to the Mystic water-supply, we desire further to state that one of us, Dr. H. J. Barnes, visited that watershed a second time in company with two members of the other committee toward the end of March of this year, and found that the tributaries to Wedge Pond and the upper Mystic were still being contaminated by the tanneries and other factories in that region in a way which cannot but be regarded as liable at any time to prove detrimental and even dangerous to the health of the consumers of Mystic water. At one, at least, of the worst tanneries discharging into the Abajonna river some efforts have been made since our first visit to ameliorate its offenses; but the devices — subsidence and filtration — adopted in most instances by those tanneries, not connected with the sewer built by the city of Boston which attempt any purification of their refuse, are entirely unsatisfactory,

inasmuch as they permit the escape of dissolved organic matter from beam-houses and hide-mills, as well as the spent liquor from vats directly into the tributary streams. At the time of our first visit a large number of privies, water-closets and sinks were discharging directly or indirectly into Russell Brook (a branch of which is known as Stink Brook), and into Town Meadow Brook. These brooks flow through thickly settled portions of the town of Woburn and empty, the former into Wedge Pond after a course of half a mile, the latter immediately into Horn Pond; the contents of both, therefore, find their way pretty directly into the upper Mystic Pond. In their last report, dated December 31st, 1885, the Boston Water Board say: Considerable attention has been given to the removal of sources of pollution; but the increase of the population and the character of the business done upon the water shed of the Mystic supply make this a more difficult problem each year.

They are now of the opinion that the sources of danger from privies, water-closets and sinks have been abated, and we can only hope that this opinion is well-founded.

The basin of the Mystic is, however, so thickly populated that, even when the inhabitants take the trouble to discharge their waste into cesspools, the soil can hardly be expected to depurate it before it reaches the streams by the subsoil currents.

The Boston Water Board contemplate the abandonment of the Mystic water-supply, and in the opinion of your committee it must come to that. In the mean time, until other sources of supply can be secured, if such should prove to be required, it would seem desirable that such connection should be made with the water-supply on the south-side of the Charles River, if practicable at a reasonable expense, as would bring the Sudbury River and Cochituate supplies within the reach of the inhabitants of the Charlestown district, within short notice — should an emergency arise.

Your committee have naturally considered the question submitted to them by you from the point of view of the physician and sanitarian. They desire again, however, to state that they are fully conscious of the complexity as well as of the importance of the problems presented.

They pray to be discharged.

GEORGE B. SHATTUCK, M.D., *Chairman.*
HENRY J. BARNES, M.D.

The report of the Committee was accepted, and the Committee discharged. The secretary was directed to place a copy of this report in the hands of His Honor, the Mayor, as supplementary to the reports previously rendered to the medical societies and transmitted to the Mayor.

— By a decree of the Roman Inquisition, dated May 19, 1886, and confirmed by the Pope, Catholics are forbidden to join cremation societies, or to order their own or the bodies of others to be cremated. His Holiness, in confirming the decree, condemns the "detestable abuse of cremating human bodies."

— A contemporary calls attention to an advertisement extolling the virtues of a new make of infant's feeding-bottle, which winds up as follows: "When the baby has done drinking, it must be unscrewed and laid in a cool place, say under a tap." Poor baby!

AMERICAN OPHTHALMOLOGICAL SOCIETY.[1]

THURSDAY. — SECOND DAY. — MORNING SESSION.

THE meeting was called to order at ten o'clock.

The first paper read was entitled

THE AMBLYOPIA OF SQUINTING EYES: IS IT A DETERMINING CAUSE OR A CONSEQUENCE OF THE SQUINT?

by S. THEOBALD, M.D., of Baltimore.

He criticized the views of Alfred Graefe and Sweigger that the amblyopia exhibited by squinting eyes is a congenital effect and argued in favor of the older view that the amblyopia is secondary to the squint and due to the mental suppression of the visual image formed in the squinting eye. He stated in the first place that it is a mistake to call this variety of amblyopia "amblyopia exanopsia," as the amblyopia is not due simply to want of use of the squinting eye, but to an active cerebral process which induces a much more rapid loss of vision. Schweigger and Alfred Graefe who both accept the theory of acquired retinal identity, believe that squint is often due to a non-establishment after birth of retinal identity. If this were the case, as there would be, from the first, no stimulus to binocular fixation, the squint ought to develop in early infancy, whereas it is rarely met with then, but usually makes its appearance about the fourth or fifth year. They both also lay stress upon the fact that some squinting eyes (even where there is no alteration), retain good vision for years, while others, which have squinted but a short time, are highly amblyopic and that this contradicts the theory that the amblyopia is produced by the squint. These observations however, do not conflict with the suppression theory, for as the amblyopia doubtless develops during the forming stage of the squint, it is reasonable to suppose that in some cases it will have reached a high grade by the time the squint is fully established, while on the other hand, a marked difference in the refraction of the two eyes (because then the diplopia will be less annoying,) will explain the retention of vision in the squinting eye.

The most convincing argument, however, in favor of the suppression theory is that the peculiar regional characteristics which the amblyopia exhibits are of just such a nature as we should anticipate if this hypothesis be the correct one, but entirely inexplicable if we suppose the amblyopia to be a congenital defect.

Until more convincing evidence is adduced to sustain the congenital amblyopia theory, it was suggested that we ought to act upon the older theory, that the squint produced the loss of vision, and so give to our patients the benefit of an early operation for the correction of this deformity.

DISCUSSION.

DR. H. D. NOYES, of New York. I differ entirely from the conclusions presented in this paper. My objections are based upon an experience and careful observation for a number of years. It has been claimed that before the development of the squint such patients have had binocular vision. There is no proof of this and the evidence is against it. Again, I have the records of a large number of cases of monocular amblyopia, presumably of congenital origin, without lesion demonstrable by the ophthalmoscope, which

[1] Concluded from page 162.

have had no squint although they may or may not have hypermetropia. Binocular fixation after operation is not infrequent, but according to my experience binocular vision is obtained in only one-fifth of the cases. It is rare to find material improvement in an amblyopic eye after operation.

Dr. O. F. Wadsworth, of Boston. I agree with what Dr. Noyes has said. After a careful examination of this subject, ten years ago, I convinced myself that the amblyopia of squinting eyes was not due to disuse. At that time I thought that I was alone in that view, but on looking up the literature of the subject, I found that Schweigger had said the same thing some years before. I think that after operation, there is no decided improvement in vision. It is sometimes said that there is, but this is largely due to the fact that the vision was not carefully measured before the operation. I have never been able to increase the vision to any extent after operation.

Dr. George C. Harlan, of Philadelphia. It has been my experience that vision is not materially improved by operation. I have at times attempted to compel the patient to use the affected eye by keeping the fixing eye under the influence of atropia for a long time. In some cases, I have succeeded in improving the vision in the amblyopic eye. I recall one case in which the vision was increased from $\frac{20}{cc}$ to $\frac{20}{i}$. Some two years later, this was still retained, the axis having become straight under the use of correcting glasses.

Dr. W. F. Mittendorf, of New York. In those cases where there is a central scotoma we can not expect any improvment from an operation, but there are certain cases in which vision is at once improved. I have thought that this was to be explained by the removal of the undue pressure exerted by the internal and external recti muscles, which is different from that exerted by the superior and inferior recti. Taking away this pressure, puts the eye in a more favorable condition and we should expect better vision.

Dr. Samuel Theobald, of Baltimore. I regret that Dr. Noyes was absent when the early part of my paper was read, for I have taken up the objections which he has brought forward.

In regard to the restoration of binocular vision my test has been as follows: If we cover the eye which formerly squinted, we find that there is still a balance of power in the internal rectus. If the amblyopia is not of too great a degree, the patient is directed to fix his eyes on a certain object. The squinting eye is then covered and it at once turns in. When the covering is removed it again turns out showing that it did so to obtain an image upon a corresponding point of the retina. To my mind, that is conclusive evidence of the restoration of binocular vision. In regard to vision, I assert that where there is a considerable amount of amblyopia, there is no appreciable improvement after operation, but this has no bearing upon the question whether the amblyopia is congenital or due to suppression.

Dr. B. Alexander Randall, of Philadelphia, reported

TWO CASES OF SEVERE TRAUMATISM OF THE EYE WITH PARTIAL DISLOCATION OF THE CRYSTALLINE LENS.

In the first case, a man of fifty, there were three points of rupture of the sclera visible on the upper surface of the globe, with some tendency to hernia of the contents. The upper half of the lens was in the anterior chamber in front of the iris, the lower half apparently being in nearly the normal position. Its extraction was advised, but delay being asked, the operation was deferred. The lens receded under rest in bed and other appropriate measures. The scleral rupture healed and in spite of disseminated opacities in the lens and in the vitreous, which prevented at any time a view of the eye-ground, the vision increased to about one-thirtieth of the normal. The patient has since been at work and fairly comfortable, the other eye giving no suggestion of sympathetic trouble. The injured eye shows little tendency to grow worse, although the lens is still luxated backwards.

In the second patient, a boy of twelve, the lens was less markedly luxated, but the ophthalmoscope showed two rents in the choroid, the larger, a little outside of the macular region, the other close to the temporal margin of the optic disk. In connection with the latter there was a reddish area of choroid, embracing the upper and inner border of the disk, where the force had apparently been insufficient to rupture the membrane, but had given it a twist causing its inflammation and subsequent atrophy. The case progressed to an excellent recovery. The vision which had been lost improved to $\frac{6}{12}$M+, and the accommodation to the extent of some five dioptrics. The choroid rents healed with little but pigmentation to mark their sites.

The eye which had shown a high degree of myopic astigmatism, probably by reason of the dislocation and rotation of the lens, returned to the approximately emmetropic condition of the other eye. The early and late appearances of the eye ground were illustrated by colored sketches.

The next paper was on

BADAL'S OPERATION. LACERATION OF THE INFRA-TROCHLEAR NERVE FOR THE RELIEF OF GLAUCOMA, ETC., WITH CASES,

by J. S. Prout, M.D., of Brooklyn.

In 1882–83 Badal, of Bordeaux, proposed the laceration of the infra-trochlear nerve (*nerf nasal externe*, of the French), for the relief of glaucoma accompanied by pain. He selected this nerve because it is the direct extension of that branch of the ophthalmic, the nasal, from which the eye-ball receives its nervous supply. It emerges from the orbit, just below the insertion of the pulley of the superior oblique muscle and supplies the skin at the root and side of the nose and the caruncle, lachrymal sac and nasal duct. It is readily reached by an incision along the margin of the orbit running from the pulley to the upper margin of the tendon of the orbicularis muscle. It is small, soft, not easily recognized, lies on the periosteum and is to be taken up by a hook with its accompanying vessels and stretched and torn by pulling directly forward. Very little bleeding occurs. Sutures are used to close the wound which under ordinary dressing soon heals. Small painful nodules are sometimes left at the point of rupture. No anæsthetic is needed as the time is short and there is but little pain except when the nerve is torn. The rationale of the operation is not explained.

In severe cases, when a short delay may be fatal to the eye, he advises that the operation be combined with evacuation of the aqueous humor. A great advantage of the operation is that, as it does not attack

the eyeball, it will be accepted by patients much more willingly than a sclerotomy or iridectomy. Four of his patients assented to it only on condition that the eyeball should not be touched. When it has failed, he has not had better results from other operations.

Badal, in 1883, reported his results in twenty operations on eighteen patients, nearly all of whom were unpromising for any operation. Pain was relieved at once in ten cases, rapidly in one, gradually in five, not stated in four. Tension was relieved quickly in four, gradually in eight, not relieved in six, not stated in two. Sight had been long lost in seven, it was improved in four, not improved in four, and not stated in five.

Dr. Prout has performed the operation nine times on five patients, which he reported. All were unpromising cases. In one there was for a time, decided improvement of vision; in one there was temporary relief from moderate, and in one from severe pain; one was a case of glaucoma simplex, operated on without benefit, another a case of hæmorrhagic glaucoma, not benefitted. Others have reported much better results. In the *American Journal of Medical Sciences* for July, 1886, Dr. C. S. Bull refers to a paper by Lagrange, who strongly commends the operation, as efficient, especially against the symptom, pain.

Dr. Prout drew the following conclusions: the operation has been shown to deserve further trial, especially in cases unfit for operations on the eye-ball, it cannot make matters worse as to the eyes; relief of pain, even if only temporary, is worth procuring at the cost of so slight an operation; it is important that cases be recorded so that its value may be ascertained.

DISCUSSION.

Dr. C. S. Bull, of New York. In my cases where the operation was performed for the relief of pain in glaucoma or ciliary neuralgia, while the relief was marked immediately after the operation, it was temporary only and in every case returned.

ADVANCEMENT OF TENON'S CAPSULE IN STRABISMUS,

by H. Knapp, M.D., of New York.

This operation was devised by de Wecker five years ago. He performed it in the following manner: A piece of conjunctiva, five millimetres long and ten millimetres high, is detached from the region of the insertion of the tendon as a centre, leaving a small band near the cornea. Tenon's capsule is now incised near the insertion of the tendon and loosened alongside of and under the muscle. The capsule is then stitched forward by two sutures, entering through the conjunctiva to the capsule at the lower and upper edges of the muscle and coming out in the conjunctiva above and below the cornea. The greater the piece of capsule loosened and stitched forward the greater the effect. If the effect appear too great, the stitches are removed the next day. If not, they are allowed to remain four or five days. De Wecker used capsular advancement for cases of insufficiency to strengthen the weak muscle, and for high degrees of strabismus, both convergent and divergent.

Dr. Knapp, during the present summer, had done the operation ten times. His operation differed from that above described in leaving a broader conjunctival flap and in using a third middle suture. His intention was to advance the whole anterior portion of the vertically folded muscle and the capsule and produce plastic inflammation which through subsequent cicatrization will shorten the parts. The operation was performed in two cases of convergent strabismus due to paralysis of the external rectus. In these cases the operation caused decided improvement.

The eyes could be approached to within four millimetres of the outer commissure. The formerly paralyzed external muscle had gained a considerable degree of power. The operation was performed on two cases in which former tenotomies had not overcome the difficulty. The operation was followed by improvement in both cases. In six cases, the operation was performed for convergent strabismus of high degree with considerable amblyopia. The results have all been quite good.

In none of the cases has there been any alarming reaction, although there was for some weeks redness and swelling in the region of the advanced capsule. At first Dr. Knapp had used catgut sutures, but one gave way on one occasion and since then he has employed black-silk sutures. Antiseptic precautions have been employed in all cases. The speaker preferred advancement of Tenon's capsule to simple advancement of the tendon, because the operation is simpler and attended with less risk. The preservation of the natural attachment exposes the muscle less to inflammation and there can be no undue retraction in cases of failures. His experience with limited advancement of Tenon's capsule has been quite encouraging.

DISCUSSION.

Dr. George C. Harlan, of Philadelphia. Does Dr. Knapp consider this a safe operation? Four or five years ago I did the operation a number of times and was much pleased with it until I had a case of pan-ophthalmitis. Of course antiseptic precautions were not employed at that time.

Dr. H. Knapp. I considered it a dangerous operation a year ago, but my views have changed considerably since then. Under antiseptic precautions, the danger is much lessened. Where suppuration occurs within the first twenty-four hours, it is certainly the result of infection, and not due to the traumatism alone.

A CASE OF TUMOR OF THE LEFT OCCIPITAL LOBE,

by Dr. Emil Gruening, of New York.

The chief interest in the case lay in the fact that the disease of the brain was localized by the existence of homonymous hemianopsia. Diagrams showing the course of the optic fibres were shown. At the autopsy a hard mass was found in the left occipital lobe and the whole cortex of this lobe was destroyed.

NEW FORMATION IN THE VITREOUS OF BOTH EYES,

by Dr. J. S. Prout, of Brooklyn.

The patient was a young man, aged twenty-six. He had never had any trouble with the eyes. In the right eye there is a band arching forward. There is no evidence of any relation to the papilla. The speaker thought that in all probability it was a remnant of the fœtal circulation of the vitreous. In the left eye there was a similar band. Drawings showing the appearance presented were exhibited.

Dr. Edward Jackson, of Philadelphia, presented a

LENS SERIES FOR THE REFRACTION-OPHTHALMOSCOPE.

Dr. John Green exhibited and described a new

SERIES OF TEST-LETTERS.

DR. CHARLES A. OLIVER, of Philadelphia, presented a

SET OF METRIC TEST-LETTERS,

and words for determining the amount and range of accommodation. They are made of six sizes of differently arranged words; each word contains three or four of the seven letters, C, D, E, T, O, L, F. Each letter is made in exact conformation with the Snellon basis. The adoption of such a series puts the determination of the acuteness of vision and of accommodation upon a uniform basis.

A CASE OF RETINITIS ALBUMINURICA: INDUCED PREMATURE LABOR,

by DR. S. D. RISLEY, of Philadelphia.

The patient, the wife of a physician, was seen September 24, 1884. She was between the fourth and fifth month of pregnancy. She had suffered with headache and giddiness. The urine had been examined a week previously and no albumen found. At this time there was marked disturbance of vision. In a previous pregnancy she had had albuminuria, but no trouble with sight. In the second pregnancy there had been no trouble.

The ophthalmoscope showed albuminuric retinitis of both eyes. The urine contained a large quantity of albumen. After standing two days, the albumen constituted four-fifths of the entire contents of the test-tube. After consultation with her husband and Dr. William Goodell, the induction of abortion was advised, but to this the patient positively refused to consent. Finally, after consultation with her clergyman, she consented.

Labor was induced, and she was delivered of a fœtus at five months. She then passed into an unconscious condition, in which she remained four days. There were no convulsions as consciousness gradually returned; evidences of right hemiplegia with aphasia was noted. The quantity of albumen gradually diminished. Six months later the lady was able to return to the office. There were still some traces of aphasia. Vision was greatly improved.

The object in reporting the case was to put on record an additional experience in this problem presenting so many serious considerations.

DR. B. ALEXANDER RANDALL exhibited a

MODIFICATION OF THE LORING OPHTHALMOSCOPE,

which consisted in adding a series of cylinders from .25 D. to 4 D.

THE FREQUENT INSTILLATION OF A TWO PER CENT. SOLUTION OF NITRATE OF SILVER IN PURULENT OPHTHALMIA,

by DR. J. A. ANDREWS, of New York.

He had employed this method in thirty-five cases of gonorrhœal ophthalmia, and the eyes were seriously damaged in none of them. The cases were all severe, with much discharge, chemosis, and swelling of the lids. The applications were repeated usually three times a day, sometimes as often as five times per day. The use of the nitrate of silver is graduated to the amount of hyperæmia, and especially to the amount of swelling of the lids. If this is marked, I do not fear to repeat the instillations frequently.

DR. RUSSELL MURDOCH, of Baltimore, exhibited an impervious covering for the sponge in the administration of ether.

MEASUREMENT OF ASTIGMATISM BY THE OPHTHALMOMETER OF JAVAL AND CHIOTZ,

by DR. H. D. NOYES, of New York.

The instrument is useful for purposes of rapid determination, for confirmation, and in doubtful cases of diagnosis.

Dr. H. D. Noyes also read the following papers by title:

BURNS OF THE EYE BY FULMINATE OF SILVER AND FULMINATE OF MERCURY.

CASES OF FOREIGN BODIES IN THE GLOBE, INCLUDING TWO CASES OF SPONTANEOUS EXTRUSION.

The officers for the ensuing year are as follows: *President*, Dr. William F. Norris, of Philadelphia; *Vice-President*, Dr. Hasket Derby, of Boston; *Secretary and Treasurer*, Dr. O. F. Wadsworth, of Boston; *Corresponding Secretary*, Dr. J. S. Prout, of Brooklyn.

The next meeting will be held at the Pequot House, New London, Conn., on the third Wednesday of July, 1887.

Adjourned.

ANNUAL MEETING OF THE AMERICAN NEUROLOGICAL ASSOCIATION.[1]

JULY 21, 22, 23, LONG BRANCH, N. J.

THURSDAY, JULY 22.

DR. C. L. DANA, of New York, read a paper on

PSEUDO-TABES FROM ARSENICAL POISONING.

The reader remarked that the first object of his paper was to report two somewhat unique cases of arsenical paralysis presenting the symptoms of tabes dorsalis. Next, to show that arsenical paralysis, like paralysis from diphtheritic poisoning and from alcohol, presents two types. One might be called the mixed or ordinary form, and the other the ataxic form. And to show also, if possible, that the ordinary teaching that arsenical paralysis is due to a diffuse myelitis is not correct, and that these paralyses are really the result of a multiple neuritis.

The conclusions arrived at were:

(1) That a disease resembling locomotor ataxia may be caused by arsenic given medicinally, absorbed from wall papers, or taken in a single large dose.

(2) That arsenical paralysis of this type, and arsenical paralysis of other types are not due to a diffuse myelitis, as has been taught, but to a multiple neuritis.

(3) That arsenical paralyses, like those from diphtheria, alcohol, and probably other infections and poisons, are of two types.

(a) The ordinary mixed motor and sensory paralysis.

(b) The pseudo-tabic form, in which there is no pronounced motor paralysis, but marked sensory troubles, especially ataxia.

DR. MILLS said the subject of arsenical paralysis was one in which he was especially interested. In referring to the case which Dr. Dana mentioned, and which he (Dr. Mills) had reported, he said that the case was one of poisoning from Paris green, and that since

[1] Continued from page 166.

then he had reported a series of cases. He thought that in these cases of metallic poisoning the true way was, not to regard it as a myelitis, neuritis, or myositis, but to look at it as a protoplasmic poisoning. That the poison, as the causing agent, affects the nervous protoplasm in varying degrees, according to the circumstances, and although Dr. Dana had asserted his reasons for regarding this disease as a neuritis, he regarded it as a myelitis. In the case just mentioned, other members of the family partook of the poison; one died with symptoms of encephalitis, one or two came near being permanently paralyzed, and others remained with the symptoms of neuritis; this, Dr. Mills thought, indicated that a broader and better generalization be taken.

Dr. Sinkler stated that he could recall some points in the case Dr. Mills mentioned; there was atrophy of the muscles of the upper extremities, atony of the bladder, marked reaction of degeneration, but the patient suffered no pain.

Dr. Mills regretted he could not substantiate Dr. Sinkler's remarks, but he thought the patient suffered considerable pain, and anodynes were used largely.

Dr. Jacoby stated that he had reported a case of lead-poisoning in which the diagnosis was very difficult indeed. The diagnosis was pseudo-tabes, due to lead-poisoning. He had expressed his opinion that the ataxia was due to a lesion in the cord; that view he now desired to correct. He would now say it was a multiple neuritis, due to lead-poisoning. The patient recovered completely, with absolute return of the patella-tendon reflexes.

Dr. Sachs remarked that, in speaking of these cases, they were called arsenical and lead poisoning, as though the symptoms were similar; these poisons have also been compared to the poisoning in diphtheria. Now, as we know that in infections the poison spreads to the most distant parts of the body, why should it not, in these cases, be peripheral, as well as central?

Dr. Mills thought arsenical-poisoning could produce a neuritis, but myelitis or cerebritis more often occurred.

Dr. Dana, in closing the discussion, stated that perhaps he had put his case rather stronger than he had intended, but the ordinary teaching was that arsenical-poisoning produced a myelitis. The main point he desired to bring out was that there is a form of the disease resembling locomotor ataxia; he thought this should be known. He also wished to show that arsenical-poisoning can bring about a multiple neuritis.

Dr. Sinkler read a paper on

THE TREATMENT OF FACIAL SPASM.

He entered at length into the results which have been secured by others in such cases, quoting an interesting case that came under his observation, in which the biceps of the right arm was also affected. All the teeth upon the right side of the mouth were removed, but gave no relief. Gelsemium, cannabis-indica, quinine, eserine, nitro-glycerine, and electricity were used, but without any marked result; in fact, the pain now extended to the right thigh and leg. The operation of stretching the facial nerve was decided upon after consultation. From the date of the operation up to the present time there has been no spasm; the force used in the stretching of the nerve was estimated to be about twenty-five pounds. When Dr. Sinkler saw the patient, about four weeks after the operation, the right side of the face was palsied, she could not shut the right eye, and the corner of the mouth hung down; but she assured him she was willing to remain that way, rather than return to the former terrible twitching. Dr. Sinkler thought, in this case, the disease was of peripheral origin, and that in such cases, after therapeutic measures have failed to relieve, the operation of stretching should be performed without any unnecessary delay.

Dr. Massey remarked that he had seen a case a few days since which was first brought to him a year ago. He had, at that time, applied the galvanic current, and during the following year the patient had been entirely free from pain.

Dr. Dana thought statistics were rather fallacious; also that some cases might get well with a slight operation, or perhaps none at all. It must be taken into account that the case mentioned by Dr. Sinkler had only been operated upon four months ago.

Dr. E. D. Fisher, of New York, read a paper on

REMARKS ON EPILEPSY,

enumerating the various phenomena occurring during convulsions. He relied chiefly upon the use of bromides for the relief and cure of the disease.

Dr. Sachs read a paper, entitled:

INTRACEREBRAL HEMORRHAGE IN THE YOUNG.

After referring to the increased attention neurologists are paying to the cerebral accidents of children, the writer recorded his conviction that intracerebral hemorrhage is more frequent in children than it is generally supposed to be, and that many cases of this sort are classified under the head of meningeal hemorrhage. Dr. Sachs then reported two cases of intracerebral hemorrhage, one in a boy two and a half years of age, and the other a young man of nineteen years. The first case was given in full in order to place the diagnosis upon a firm basis. The child had typical right hemiplegia with aphasia without coma or convulsions at the time of onset. The onset was slow, aphasia setting in first, paralysis of the arm and leg some hours later. The recovery was typical of that which takes place in many cases of adult hemiplegia from apoplexy.

The reasons were given why the writer held that in this case the apoplectic attack was due to hemorrhage rather than to embolism or thrombosis. As regards the differential diagnosis between meningeal and intracerebral hemorrhage, the lack of convulsions seemed to be of unusual significance. In meningeal hemorrhage, convulsions are invariably present and their absence might argue, other things being equal, in favor of intracerebral hemorrhage. In the second case the young man had had two apoplectic attacks, exactly one year apart. The histories of these attacks were very similar to the one given in the first case. In the first mild attack all symptoms developed and ended typically. In the second attack the onset was slow, there was coma lasting for over eighteen hours, and recovery was not complete, contractions having set in in the affected arm. No convulsions at any time. There was no specific history.

Using these two cases as a basis, the author of the paper entered upon a discussion of the changes in the walls of the cerebral arteries, permitting an effusion of blood into the brain substance. Autopsies on this condition are very scarce, but there is good reason for supposing (reference was here made to some recently

reported cases of Dr. Osler) that miliary aneurisms occur in young children, and that fatty degeneration of the cerebral arteries (permitting transudation of blood through the vessel-walls — Recklinghausen) is not an infrequent condition:

Discussion was invited on the following points:

(1) Frequency of intracerebral as compared with meningeal hemorrhage in young persons not the subjects of specific disease.

(2) The value of convulsions as a factor in differential diagnosis.

(3) Pathological changes in the walls of the cerebral arteries in the young.

Dr. Mills thought that intracranial hemorrhage occurred in the young more frequently than was imagined. He had made three autopsies in children from the same family, all three of whom had died within a few days after birth; he found extensive meningeal hemorrhage in all these cases.

Dr. Lloyd then quoted two cases occurring in young men, one eighteen years of age and the other less. In one case it followed close upon an attack of diphtheria; in the other, the elder, the patient complained in the morning of not feeling very well, and was compelled to go back to his bed. When Dr. Lloyd saw him, he had passed into coma with convulsions on the right side of the body. In this case the patient was a confirmed inebriate. When first seen, coma and convulsions had set in, there were waves of spasms sweeping over to the paralyzed side, there was also extreme lateral deviation of the eyes; right facial paralysis, face being drawn to the left side. Dr. Lloyd was a little puzzled about the case, as he did not expect to find a confirmed drunkard at the age of eighteen years. The boy died in a few hours and the case had to be handed to the coroner. At the autopsy there was absolutely nothing found which would account for the conditions mentioned.

Dr. L. Zenner thought in these cases it was difficult to tell except by the autopsy, whether it was hemorrhage, thrombosis or embolism; he considered that mere symptomatology was not sufficient in these cases for a diagnosis to be based on.

Dr. McNutt spoke of a case in which there were convulsive movements on the body and face of the same side. At the post-mortem the brain was examined very carefully, but there was simply œdema of the brain; there was no hemorrhage on either side of the brain.

Dr. Amidon thought the lesion might occur in the circulatory apparatus, more especially the arteries. The most natural thing to look for would be miliary aneurism as remarked by Dr. Sachs, although he was inclined to think that that was a disease of adult life. He has seen pathological specimens where the aorta was narrowed, the patient dying very suddenly from inter-cerebral hemorrhage. Barié has reported twenty-seven cases in which he states the narrowing of the arteries is almost always below the origin of the left subclavian artery: some of the patients previously suffered from vicarious menstruation or epistaxis.

Dr. Sachs begged attention to a fact in regard to prognosis. He thought it made a great difference whether the child suffered from convulsions or not.

Dr. Zenner, of Cincinnati, presented a case of

AUCTIONEER'S CRAMP,

remarking that it came under that large group of cases termed professional neuroses, which generally affected the muscles of the extremities, but in this case the muscles of the face only were involved, mainly if not entirely those of articulation, and as far as he knew nothing similar had been reported, and, therefore, he thought it of great interest to the profession. The doctor then gave the following history:

Patient a male, 45 years of age, of good family history, had always had excellent health, following the occupation of an auctioneer. In March, 1885, was confined to his house for a month with an ulcer upon one of his legs; during that time his health, with that exception, was good. He had been an exceptionally busy man, calling sales from morning till night, often refusing to leave the sale to obtain his lunch. After recovering from the ulcer and resuming his calling he noticed at the first sale which he cried that he had some difficulty in his articulation but it was not such as to cause him to desist from speaking. After three or four successive sales, during which time the difficulty kept increasing, he was compelled to abandon business entirely. He now began to notice occasional slight difficulty in articulation in ordinary conversation and also some subjective symptoms consisting of a sense of fatigue of the muscles after talking, a sense of throbbing and a dragging sensation at the left corner of the mouth. Dr. Zenner saw him about a month after these symptoms were first felt. At that time there was considerable general nervousness shown, further than this there have been no symptoms of disease, his general health being excellent. His weight is about the same, appetite fair and sleeps well, general motility on application of electricity normal, as are also the tendon-reflexes.

Dr. Zenner presented the patient and drew attention to the fact that when the face was in a state of rest, there was a certain increase of depth of the nasal fold and a drawing-in of the left corner of the mouth, which was due to a tonic spasm; the patient also felt a certain sense of pressure there, as though the cheek were pressed against the teeth. In ordinary conversation the contraction of the muscles are scarcely visible, in fact some of his acquaintances have not noticed anything abnormal.

Dr. Zenner then requested the patient to call five rapidly as in calling a sale. On the rapid repetition of the word the contraction of the muscles upon the left side of the face was very marked, these being tense like a rigid band while the right corner of the mouth was drawn upward making it almost appear as though the contraction of the muscles was upon the right side of the face while the left to an ordinary observer would appear almost normal; the patient also complained of a sense of very painful fatigue on the left side of the face. The orbicularis oris in this case seemed to be the muscle principally involved, but the other muscles were somewhat affected. Dr. Zenner also stated that the patient himself had discovered that by putting the end of a pencil under the lip and pushing it upward to remove the tension he could be much relieved and could articulate much better (this effect was proved by the patient before the meeting). In this case electricity, massage and manipulation have been applied. The muscles respond to the current as promptly upon one side as the other, but this treatment has effected no very satisfactory results.

Dr. Wilder remarked that from where he was

sitting the difficulty seemed to be upon the right side of the face.

DR. JACOBY said the same idea had occurred to him.

DR. VAN BIBBER asked if the patient ever had any previous affection of the face or ears.

DR. ZENNER replied that he had not, and that the first thing he had noticed was a slight heavy aching feeling in the left corner of the mouth, which had gradually increased. Dr. Zenner thought that the muscles of the affected side being brought so constantly into action by one continual effort might account for the condition of subjective symptoms presented. Poore, in his analysis of cases of writer's cramp speaks of the neurosis being due to a persistent activity of certain muscles where the act of prehension is brought into play; this somewhat resembles the present case in requiring greater than ordinary effort. The patient himself has never accepted the fact that his calling of sales has produced his difficulty, but rather attributes it to having taken cold while confined to his house for that month, as he was in the habit of sitting by an open window. Dr. Zenner did not dispute that there might be some other elements involved. He concluded that although he had administered the iodides, electricity, etc., that if these were pushed a little further, together with more thorough application of massage and electricity and no better results secured, it would be advisable to resort to stretching of the facial nerves of the left side.

In answer to questions Dr. Zenner replied there were no contractions in drinking unless an effort was required, and no specific history so far as he had been able to learn.

DR. L. C. GRAY inquired if he had been examined by the opthalmoscope.

DR. ZENNER stated that he had sent him to a specialist for that purpose, and there was nothing abnormal in that respect.

DR. GRAY then asked if, on examining him with galvanism, any difference was observed in the contraction of the muscles.

DR. ZENNER replied not in the orbicularis oris, to which he had specially directed his attention.

DR. LLOYD asked if the patient suffered from vertigo.

DR. ZENNER replied he did not.

THE PRESIDENT remarked that the case was one of extreme interest, and that he was inclined to regard it as a professional neurosis, and cited a case in which he had been called in consultation by Dr. C. U. Turnbull, of Philadelphia. The patient was an actor playing in the Mikado at one of the theatres; this man was compelled in his part to distort his face to a peculiar expression requiring great effort. The result of this effort was followed by double vision, which at last compelled him to seek Dr. Turnbull's advice; he was then suffering from paralysis of one of the external recti muscles. There was one peculiarity, and that was that, with an increased voluntary effort, the patient could draw the affected eye into its normal position.

DR. MILLS thought cerebral exhaustion was a factor in this condition, and stated that although this condition lasted some time, the patient had almost recovered.

Dr. Mills also thought this patient of Dr. Zenner presented appearances of secondary contractions, and that this condition was extremely difficult, if not almost impossible to alleviate. The case presented symptoms which he had observed in cases of peripheral neuritis, which had spread and involved a large part of the muscles of the face, and he thought that a slight peripheral neuritis might have been the starting point. The question was whether it was central or peripheral, and if central, whether a disease of the nuclei or the higher centres. Dr. Mills thought the line of treatment suggested by Dr. Zenner very good, rest to the parts and an endeavor to restore nutrition being most desirable; he also thought that if recovery was delayed under these conditions, stretching of the nerve should not be postponed too long, and that stretching of the facial nerve was distinctly indicated when other means failed.

DR. GRAY remarked that he had made a diagnosis of lesion of the facial nerve, and asked if there were any symptoms of aphasia.

DR. ZENNER replied that the patient had never lost the pronunciation of a word.

DR. GRAY remarked it would require a most careful examination by the electric current to form a differential diagnosis, but he had thought, while making his examination, there was a difference of power of the two sides, and that the patient was paralyzed on one side of his face; that there was a difference in the closing of the eyes, and also, when the patient closed his lips upon the speaker's fingers, there was evidently a loss of power upon the left side.

DR. ZENNER, in closing the remarks, said that he would not deny that there was or had been neuritis present, though there was no direct evidence of it, no apparent paralysis or degenerative electrical reactions. He had not pretended to say what was the exact seat or nature of the disease in this patient. In most cases of professional neuroses the nature of the disease is altogether obscure; probably there may be a different pathological basis in different cases. In a number of cases of writer's cramp neuritis appeared to be the cause. But that his own case was properly classified with professional neuroses was based upon the features peculiar to almost all such cases, first, that it seemed to have as its cause the excessive use of the affected muscles, secondly, that the peculiar symptoms were brought out, in each instance, only when those muscles were brought into play by a voluntary act.

When the patient attempts to repeat a word rapidly there is a rigid contraction of the muscles at the left angle of the mouth, pressing it firmly against the teeth, and at the same time some of the muscles on the right side contract, though much less forcibly, pulling the mouth toward the right side. The elevator muscles of the left upper lip alone take no part in the spasm, so that it appears as if there were paralysis of that side of the face, and the face is merely drawn to the other side. But the patient revealed that there was no paralysis of these muscles by exposing upper and lower teeth, by moving the mouth to one side and the other, all of which was as well done on the left side as right. The strength of the elevator muscles of the left upper lip was farther shown by the patient's holding the lip elevated while the examiner made forcible and persistent efforts to pull it down.

The speaker has repeatedly examined the patient for paresis of some of the muscles, which is often the basis of spasms of various kinds, as in cases of writer's cramp and in other kinds of spasms, but has never been able to detect any marked weakness of any of the muscles.

(To be continued.)

THE REPARATIVE POWER OF THE AGED.

THE attempt to give a prognosis as to the duration of life in an old person in whom there is no actual disease, but who is approaching what some one has felicitously termed physiological death, is often a difficult matter. Friends who wish to be present at the closing scene inquire whether they may safely go away for a day or a week with the expectation of finding the patient living when they return, and it often happens that the physician's best judgment as to the patient's probable capacity for holding out is sufficiently at fault to cause the friends the needless relinquishment of business or other plans, for a considerable time before the dissolution takes place.

As persons in whom the vital currents are not strong, often endure operations and confining accidents better than those in rude health, so there is sometimes in the aged a surprising resistance to exhausting influences. From childhood to age the ratio of the force-production to the needs of the economy is constantly growing less, till the surplus available for repair and growth seems well-nigh exhausted. Yet perhaps the actual demands on nutritive activity in the processes of repair are not so very great; and the condition of rest and quietness attending the diminished nerve-susceptibility of old age may be more promotive of reparatory processes than an excess of nutritive force without such quietness. It has been said that over-action is the greatest enemy to repair.

Some two years ago Dr. Humphrey, Professor of Surgery at the University of Cambridge, published the information gathered by a collective-investigative inquiry in one of the branches of the British Medical Association. In the paper containing these data the author endeavored to show that certain injuries commonly supposed to be difficult or impossible of repair in the aged, were so, not so much on account of the age of the victims as from other causes. For instance, the rare union of intracapsular fracture of the thigh, he claimed, is due to the peculiar condition of the part, to the separation of the broken surfaces, to the buried position of the inner fragment in the cavity of the acetabulum which permits the contact of the fragments as well as the formation of any uniting medium around the point of fracture, rather than to the fact of senility. The character of the fracture was compared to that of the olecranon and the patella, and it was shown that bony union takes place firmly and quickly in the aged in extra-capsular fractures, or in any others where the fragments can be kept well in contact. As to whether intracapsular fractures, which are uncommon in earlier life, do as a matter of fact heal much better than those in old age, there is apparently not much evidence attainable.

Dr. Humphrey has gathered more information on the reparative powers of the aged since his previous communication and he gives some of the results in the *British Medical Journal* for August 7. Among notable cases illustrating this point he cites the following:

"(1) James Pearson, aged 104, recovered from attacks of diarrhœa at 75 and 90, and from fractured neck of the thigh-bone at 101. In what manner the bones united cannot be determined. He goes about with crutches.

"(2) Rebecca Burn, aged 104, Dr. Whitby, of Hunstanton, relates, had injury to her hip from a fall at 96, which kept her in bed two or three months, and she quite recovered.

"(3) Fanny Covill, aged 100 and six months, whom I saw in Yorkshire, in August last, had a severe fit with loss of consciousness, for which she was bled, at 60; and, again, two fits of the same kind at 70; she quite recovered, and has had none since.

"(4) William Chappell, aged 100, had renal dropsy at 82, which lasted two years, and was cured by elaterium. He had a large slough on the thigh, from a bruise, at 99, and quite recovered.

"(5) Miss Hastings, aged 104, had acute bronchitis at 95, at 98, and 99, each time severely, had pneumonia and erysipelas of the head in her hundredth year. She recovered from all these; and, in her 104th year, had an attack (severe) of pneumonia in both lungs, which passed through its ordinary course, and, in the words of Dr. Pike, of Malvern, she threw off the disease wonderfully, and the lungs cleared up well, leaving only the chronic bronchitis, from which she had latterly suffered; but she did not again fully recover her strength.

"(6) M. L., aged 108, fractured the wrist at 104. Good callus formed, and there was complete consolidation of the fracture. (Information derived from a resident of Nantes; whether medical man not stated).

"(7) William Hodge, aged 101, had shingles at 99, and recovered.

"(8) Ann Trew, aged 101, recovered from a severe attack of bronchitis at 82.

"(9) Mrs. Pallett, aged 104, had severe fever at 84, and quite recovered.

"(10) Dr. Black, of Wimpole Street, tells me of a lady who recovered rapidly and completely from a Colles's fracture at 89, and completely from burns and scalds on the hands at 92.

"(11) Dr. Horder, of Cardiff, relates of a man, aged 92, that he has had two attacks of bronchitis and one of pneumonia in the last four years.

"(12) Dr. Campbell, of Liverpool, relates of a woman, aged 97, that she completely recovered from an attack of acute bronchitis at 95.

"(13) I was told that James Betts, aged 91, whom I saw at Norwich, had severe erysipelas of the head and face at 89, and quite recovered.

"(14) Mr. Ronaldson, of Haddington, states that a man, aged 97, had a severe attack of bronchitis at 88, resulting in complete recovery."

A clear distinction is made by Dr. Humphrey between the power in the aged of bearing up against the first impulses or initial shock of disease and that of recovering from its effects, or, as he expresses it, between the power to withstand the tidal flow of disease

and that of repair during its ebb. The depression caused by the onset of an acute malady in the aged is explained by the fact that a febrile temperature means a waste and dissipation of heat, which is exactly what old age has the greatest difficulty in maintaining. Hence the rapidity with which old people succumb to a trifling febrile attack, even a cold. But the onset having been resisted, the patient often develops remarkable reparative power, as also in the case of ulcers, wounds and fractures. Even in senile gangrene, where the nutrition of a part has been so poor that it could not keep itself alive, there is often evidence of much vital energy in the region most nearly adjacent to the separated part.

Of course when there are lesions of any portion of the nervous system, these reparative processes will not occur. Perhaps in other cases Dr. Humphrey is unduly sanguine of the resisting power of old persons, but the cases he has collected, give us warrant in hoping in the care of the aged, if we can fortify them against the first onset of an acute malady, to find in nature a strong and often unlooked for recuperative force.

FUNCTIONS OF THE THYROID GLAND.

Schiff[1] has recently published the results of numerous extirpations of the thyroid gland in animals, from which it would seem that complete thyroidectomy is not the trivial and harmless operation which it was formerly supposed to be. Maignien,[2] in 1842, published a memoir in which he pointed out what he considered as important relations between the thyroid and the intracerebral circulation, a principal office of that gland being "to compress the carotids against the vertebral column, and thus diminish the afflux of blood to the anterior parts of the encephalon," and, according to Schiff's experiments, complete and simultaneous extirpation of the two thyroids in mammals is attended with grave cerebral symptoms, and is almost invariably fatal.

Out of sixty dogs on which the operation was performed only one survived, after severe sickness, and all the others died between the fourth and twenty-seventh day of cerebral disease, the symptoms consisting "of a singular mixture of paralytic (or paretic) and irritative and convulsive phenomena." If only one thyroid was removed at a time, a considerable interval between the two operations being allowed, the symptoms were less alarming, though still grave, and the animal generally survived. The operation was performed in every case with due antiseptic precautions, and all possibility of septicæmia seems to have been excluded. Herzen has lately repeated, and with the greatest care, the experiments of Schiff, and with complete confirmation of Schiff's results. In every instance, within a limited period after the thyroidectomy, the animal was taken with rigors, convulsions, symptoms indicating hallucinations of terror, then cyanosis, coma, paralysis and death. His conclusions are as follows: "The effects of thyroidectomy really and solely depend on *absence of the thyroid*, and they are the expression of a *cerebral affection*, probably cortical."[3]

These experiments recall the paper read by Prof. Kocher, of Berne, at the Twelfth Congress of German Surgeons in 1883, on "Extirpation of Goitre and its Consequences." This paper was based upon one hundred and one cases of partial or total removal of the thyroid in man for goitre. The partial extirpations, as far as they could be followed up, were apparently followed by no unfavorable results, but of the eighteen cases of total extirpation, sixteen showed more or less considerable derangement of the general health of a distinctly progressive character, changes which eventually were highly suggestive of idiocy, cretinism and myxœdema; in the two other cases, unusual conditions were developed which may have accounted for their exceptionally favorable course.

THE SOMERVILLE POISONING SENSATION.

The recent developments in the case of Sarah A. Robinson, of West Somerville, Mass., charged with poisoning successively through a series of years seven members of her own family, the last her own son, an amiable and promising young man twenty-one years of age, indicate, if reports should be confirmed, a degree of diabolical wickedness hardly equalled since the days of Lucretia Borgia, for in this instance, the incitement to the murder of kith and kin seems to have been a cold-blooded and sordid lust for petty life-insurance moneys, and not the eager impulse of envy, hatred or jealousy. Mrs. Robinson also stands accused of other crimes of a similar nature, and we understand that arsenic in large quantities has been found in the stomach of the last of her supposed victims. She awaits her trial at East Cambridge, and if convicted on the principal charges, she will have won for herself a place in history by the side of Hieronyma Spara and the notorious Parisian poisoners of the 17th century.

Professional poisoners are apt to resort to arsenic to accomplish their purposes, and the famous Italian poison of the last century, with which the notorious Toffania is said to have caused the death of more than six hundred persons, was composed of neutral arsenical salts. The celebrated elixir of La Spara, which was secretly sold all through Europe as a sure specific for ridding husbands or wives of uncomfortable partners, and which was stated to be "a slow poison, clear, tasteless and limpid, and of strength sufficient to destroy life in the course of a day, week, month, or number of months, as the purchaser preferred," was an alkaline solution of arsenious acid.

There is also evidence that the famous "succession powder" — the secret of whose manufacture the Marquise de Brinvillers, of the 17th century obtained of

[3] Semaine Medicle, August 11th, 1886.

her lover, St. Croix, and with which she caused the tragic death of her father, her two brothers and sisters, besides hosts of other victims (according to her own confession) — was a compound of white arsenic with some inert substance. The career of the Marquise excited such terror in France that Louis XIV instituted a distinct tribunal, the *Chambre Ardente*, to investigate cases of poisoning by the "succession powder;" many persons of the first rank, such as the Maréchal de Luxembourg and the Princess Louise of Savoy, were examined on suspicion, but no one was executed except the pretended sorcerer, Voisin, in 1680, after which time there seemed to be no farther call for the "Fiery Chamber."

Moreover, that compound of less romantic associations, sold under the name of "Rough on Rats," owes its poisonous properties to arsenic, and is used not only to destroy vermin, but has frequently proved itself a too convenient tool for both suicide and murder.

MEDICAL NOTES.

— The foolhardy continue to experiment with themselves with the result of possibly throwing some light on what the human body can endure under certain severe conditions. Two men have, within a few months, gone through the whirlpool rapids at Niagara Falls, one completely enclosed in a cask built for the purpose, and another having his body below the neck similarly enclosed, but with his head left out. Last Sunday a young man made the passage with no external appliance but a life-preserver of cork buckled about his trunk. He was ten minutes in going through the rapids, and was at one time submerged for ten seconds consecutively. He reports himself to have been unconscious several times during his transit, and says that a person utterly unable to swim would stand as good a chance for his life as the most expert swimmer. He does not believe that any one could accomplish the task without the aid of a life-preserver. The only reliable life-preserver for such cases seems to be to stay ashore.

— The *New York Sun* contains the following:

Manager. "How old is your child, madam?"— *Woman.* "Eleven months, sir."—*Manager.* "Male or female?"— *Woman.* "Female."—*Manager.* "What experience has she had as an actress?"— *Woman.* "She was with Foshay's combination two months, sir, and has also played an engagement at the Madison Park Theatre."—*Manager.* "I will assign her a part in our forthcoming play, 'A Father's Crime and a Grandfather's Sin; or, the Lost Child.' First rehearsal Tuesday at 10 A. M."

That this is not altogether an "imaginary conversation" is shown by the fact stated in a newspaper interview by a dramatic star of some note, that he began his professional career in a Philadelphia theatre at the age of six weeks.

— At a recent meeting of the Central Veterinary Society of Paris, M. Nocard stated that all birds, living in contiguity with human beings, were liable to contract a bacillary tuberculosis. He had met with four poultry yards infected with tuberculosis, where the epidemic could only be accounted for in one way, and that way was contact, either direct or indirect, with persons in the last stage of phthisis. In a fifth instance of tuberculosis in a poultry-yard, the element of contagion must have existed in the excrement of tuberculous cows which was devoured by the birds. Experiments proved that inoculation or ingestion of tuberculous products taken from mammalia, rendered birds tuberculous. In tuberculosis produced by tuberculous products of animal origin, the distribution of visible lesions, and the morphology of the bacilli, are identical with those observed in cases of natural tuberculosis.

— In one of the forges of the royal gun factory at the royal arsenal, Woolwich, an appalling accident occurred while a party of men were employed in casting a great ingot of steel for the construction of an 8 6-ton gun. The mould was a cylinder standing on end in a pit of about ten feet square, and the iron floor of the pit formed the bottom of the mould. Into this was poured about eight tons of molten steel from a patent gas furnace, and the casting would have been perfect if the usual period of two hours had been allowed for its growing cool, but in about one hour after the metal had been run, a man descended into the pit to block up the mould casing preparatory to its being removed. The steel had barely set on the outside, and, as soon as the cylinder was raised from the floor, the molten metal poured out in a deluge. The man attempted to reach the ladder by which he had descended, but was caught and overwhelmed by the liquid steel. No trace of the man could be observed in the seething well, and the metal was visibly cooling on the surface, threatening to encase the remains of its victim in a solid block of steel. The men went zealously to work with iron rods and hooks and ladles, and, notwithstanding the intense heat, succeeded in extracting a shapeless mass of human cinder, which was pronounced to be a portion of the trunk. The head and limbs were not recovered but after the metal cooled some portions of them were found projecting above the surface.

Miscellany.

SALICYLATE OF COCAINE IN ASTHMA.

A COMPARATIVELY new method of treatment in asthma nervosum has lately been tried we learn from the *British Medical Journal*, July 17, by Professor Mosler, of Greifswald. It is now well known that cocaine has not only a local action on the sensory nerve-endings, but also a central one, which, at first stimulating to the nerve centres, may, if the drug be pushed, become sedative or even narcotic. By this peripheral or central effect, it may, therefore, act in

such spasmodic diseases as asthma. Early last year Beschorner published two cases of this disease which were much benefitted by cocaine. In three cases, Professor Mosler has obtained excellent results. All these cases occurred in young people of twenty-three to twenty-five years of age, and were uncomplicated by any organic heart or lung disease. The drug was given subcutaneously, in doses of 0.4 gramme, at the commencement of the attack. The first patient, who had a bad family history as regards lung disease, and in whom the asthma has lasted eleven years, was relieved after the third injection; two more doses caused abeyance of the attacks (which occurred previously every day) for a fortnight, when the patient was lost sight of. In the second and third cases, the treatment was more rapid in cutting short the attacks, which in the end were postponed for the three or four weeks during which the patients continued under observation. The injections caused, in one case, a slight sense of faintness and the appearance of dark spots before the eyes; but these symptoms soon vanished. It is, of course, impossible to draw from these cases any conclusion as to the permanent benefit of the treatment. Extended experience will perhaps show that the drug is only a palliative. It is in the hope of inducing other practitioners to try the treatment that Professor Mosler has published the results of his cases.

STATISTICS OF THE PUBLIC WARDS IN THE UNITED STATES.

THE report of Fred. H. Wines, special agent of the tenth census on the defective, dependent and delinquent classes, has been sent to the Senate, and the main points of it are given in the despatches to the daily press. The report contains a large number of interesting tables respecting the criminal and pauper classes of the United States. Among other things, it shows the total number of prisoners confined in jails, workhouses, and penitentiaries, etc., in the United States in 1880 to be 58,609, of which 53,604 were males and 5,005 females, 45,802 natives and 12,807 foreigners, 41,861 whites and 16,748 colored. The number of prisoners to each million of population is given as 1,069. In 1870 it was 853. The number of insane persons in the United States in 1880 is given as 91,959, or 1,833 for each million of population. In 1870, the total number was 37,432, or 971 for each million. Among the insane are 130 males and 138 females, who are also deaf mutes; 245 males and 282 females who are blind, and 16 males and 14 females who are deaf and dumb and blind. The number of homeless children (16 years and under) in 1880 was 57,423, of which 30,171 were males and 27,252 females; 55,613 were native born, and 18,210 of foreign birth. The number of white homeless children is given as 54,883, and that of colored as 25,040.

The number of idiots in the United States reported as receiving special training is 6,809. This idiotic class increased from 24,527 in 1876 to 76,895 in 1880. In the former year, the ratio was 636 to each million of population, and in the latter year it was 1,533. The number of the idiotic deaf mutes is: Males, 1,185; females, 937; idiotic deaf mutes and blind, males, 107; females 110; idiotic and blind, males, 661; females, 525.

The total number of blind in the United States in 1880 was 48,926, or 976 in each million of population. The number of blind reported as receiving instruction is given as 4,691. The number of blind who are also deaf mutes is: Whites, 84 males and 107 females; colored, 28 males and 29 females; blind and idiotic, whites, 595 males, 463 females; colored, 66 males, 62 females.

The number of deaf mutes in the United States in 1880, who are reported to have received special instruction in the various institutions for the deaf and dumb, is 12,154. Of any of the States, New York furnishes the largest number of this class of persons (1809), and Florida and Nevada the smallest number (six each). The Territory of Wyoming has none. The number of outdoor paupers in 1880 is given as, males, 10,290; females, 11,305; 17,902 are natives and 3,693 foreigners; 19,328 white and 2,267 colored.

The number of almshouse paupers in the United States in 1880 was: Males, 35,564; females, 30,639; of which 37,603 were white, and 5,717 colored.

THE USE AND ABUSE OF TEA.

WE make the following extracts from a leading editorial in the *British Medical Journal* (July 24), on this subject:

As might be conjectured from the nature of the physiological action of tea, the effects of its abuse fall chiefly on the nervous and digestive systems. Nervous irritability, palpitation, insomnia, and sense of brain-fatigue are among the most prominent of the neurotic symptoms; and, although it is unquestionable that these symptoms are often etiologically connected with other sources of nervous disturbance as well as tea-drinking, it is not less clear that they are greatly aggravated by the excessive use of tea. The digestive symptoms are impairment of the appetite, pain and flatulence during the process of digestion, and defective intestinal action — the symptoms, in fact, of one of the varieties of atonic dyspepsia. How far these symptoms are due to the thein contained in tea, and how far to its tannin, is a question. Sir William Roberts has shown that the most rapid infusion does not prevent the dissolving out of a large proportion of the tannin, and we are disposed to conjecture that the digestive symptoms may to a large degree be safely attributed, not to any chemical action, but to the same cause which produces the neurotic disturbance, namely, the thein.

The sufferers from excessive tea-drinking may be grouped into three classes:

First, there is the large class of pure brain-workers, who speedily discover that, while alcohol is pernicious to them, tea affords the stimulus which they desire. They indulge in it without fear of mischief, and often to an unlimited extent. Dr. Johnson's tea-drinking was proverbial, and many distinguished writers could tell a similar tale. After a time, the neurotic symptoms enumerated above begin to make their appearance, and, in many cases, do much to impair temper, and to limit the capacity for sustained intellectual effort.

Secondly, there is the large class of women of the better classes who, beginning with afternoon tea, often end by using their favorite stimulant in the intervals

between all the meals of the day, and as often as the humor takes them. The result is that appetite becomes impaired, and the prostration due to insufficient nourishment is combated with more potations of the ever welcome stimulant, until the vicious circle is well established.

Thirdly, in all our large manufacturing towns there are numbers of factory-operatives, especially women, who, finding it difficult to provide a cheap and appetizing mid-day meal, fly to the tea-pot, and do a large amount of severe physical labor on this miserable dietary. It is most important to impress upon this class, who are usually profoundly ignorant of everything concerning health and diet, that tea is not a food, and that the delusive sense of satisfaction which it bestows is a dangerous snare.

In addition to the above classes, there is a small group of persons to whom tea seems a positive poison. We know that idiosyncrasy accounts for the most extraordinary departures from the normal rule in matters of diet or the action of medicine; and the number of persons whose idiosyncrasy includes an intolerance of tea is considerable enough to make the subject worthy of professional attention.

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 14, 1886.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from				
				Infectious Diseases.	Consumption.	Diarrhœal Diseases.	Typhoid Fever.	Diph. and Croup.

Deaths reported 2,076: under five years of age 1,239: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 562, consumption 315, lung diseases 133, diarrhœal diseases 562, diphtheria and croup 96, typhoid fever 56, whooping-cough 31, measles 27, malarial fever 24, scarlet fever 21, cerebro-spinal meningitis 11, puerperal fever six, erysipelas two. From measles, New York 10, Charleston five, Baltimore three, Cincinnati, two, Philadelphia, Brooklyn, Boston, and Cambridge one each. From malarial fevers, New Orleans nine, New York six, Baltimore three, Brooklyn and District of Columbia two each, Philadelphia and Nashville one each. From scarlet fever, Pittsburg seven, New York and Brooklyn three each, Philadelphia, Cincinnati, and Providence two each, Boston and Baltimore one each. From cerebro-spinal meningitis, New York four, Pittsburgh three, Cincinnati, District of Columbia, Fitchburg, and Waltham one each. From puerperal fever, New York and Brooklyn two each, New Orleans and Providence one each. From erysipelas, New York and Brooklyn one each.

In the 19 cities and greater towns of Massachusetts, with a population of 907,642 (population of the State 1,941,465), the total death-rate for the week was 24.56 against 25.02 and 26.39 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending July 31st the death-rate was 20.6. Deaths reported 3,393; infants under one year of age 1,339; acute diseases of the respiratory organs (London) 172, diarrhœa 646, measles 83, whooping-cough 59, fever 39, scarlet fever 23, diphtheria 22.

The death-rates ranged from 11.2 in Hull to 31.0 in Leicester; Birkenhead 24.1; Birmingham 18.9; Bradford 17.6; Leeds 18.9; Liverpool 21.2; London 22.0; Manchester 21.9; Newcastle-on-Tyne 18.8; Nottingham 18.0; Sheffield 14.9.

In Edinburgh 21.3; Glasgow 20.4; Dublin 17.3.

For the week ending July 24th, in the Swiss towns, there were 25 deaths from consumption, lung diseases 10, diarrhœal diseases 18, measles three, diphtheria and croup two, whooping-cough two, typhoid fever two, small-pox one.

The death-rates were: at Zurich 5.7; Geneva 7.1; Basle 17.0; Berne 13 9.

For the week ending July 31st, in the Swiss towns, there were 36 deaths from consumption, lung diseases 21, whooping-cough six, scarlet fever two, erysipelas, typhoid fever, and puerperal fever one each.

The death-rates were: at Zurich 11.5; Geneva 9.1; Basle 28.1; Berne 21.4.

The meteorological record for week ending August 14, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, Aug. 14, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 14, 1886, TO AUGUST 20, 1886.

BAILEY, J. C., major and surgeon. Granted one month's leave of absence. S. O. 111, Division of the Atlantic, August 17, 1886.

STERNBERG, GEORGE M., major and surgeon. Granted leave of absence for fifteen days. S. O. 186, A. G. O., August 12, 1886.

BENTLEY, E., major and surgeon. Granted one month's leave of absence, and at its expiration to report for duty as post-surgeon at Little Rock, Ark. S. O. 113, A. G. O., Division of the Atlantic, August 18, 1886.

TREMAINE, W. S., major and surgeon. Sick leave further extended six months. S. O. 187, August 13, 1886.

LORING, L. Y., captain and assistant surgeon. Leave of absence granted him in S. O. 59, Division of the Pacific, August 2, 1886; extended two months on surgeon's certificate of disability. S. O. 189, A. G. O., August 16, 1886.

TAYLOR, B. D., captain and assistant surgeon. When relieved by Surgeon Bentley to proceed to Jackson Barracks, La., and report for duty as post-surgeon. S. O. 113, C. S. Division of the Atlantic.

HOPKINS, W. E., first lieutenant and assistant surgeon. Ordered from Fort Lowell, A. T., to Angel Island, Cal., for duty as post-surgeon. S. O. 61, Division of the Pacific, August 6, 1886.

WALES, PHIL G., lieutenant and assistant surgeon. Relieved from duty in the Department of Columbia, and to report in person at headquarters, Division of the Pacific, for further orders. S. O. 62, Division of the Pacific, August 9, 1886.

BORDEN, WM. C., lieutenant and assistant surgeon. Assigned to temporary duty at Fort Bridger, Wyo., during absence of Assistant Surgeon Crampton. S. O. 100, Department of the Platte, August 9, 1886.

MASON, CHAS. F., lieutenant and assistant surgeon. Assigned to duty as post-surgeon at Plattsburg Barracks, N. Y. S. O. 113, Division of the Atlantic, August 18, 1886.

PROMOTIONS.

To be surgeon with the rank of colonel:

MAGRUDER, DAVID L., lieutenant-colonel, July 26, 1886, vice Brown, retired.

To be surgeon with the rank of lieutenant-colonel:

ALEXANDER, CHAS. T., major, July 26, 1886, vice Magruder, promoted.

To be surgeon with the rank of major:

CRONKHITE, HENRY M., assistant surgeon, July 26, 1886, vice Alexander, promoted.

APPOINTMENTS.

To be assistant surgeon:

WALKER, FREEMAN V., of Georgia, July 27, 1886, vice Cronkhite, promoted.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING AUGUST 21, 1886.

STONE, Dr. E. P., commissioned an assistant surgeon in the Navy, August 5, 1886.

WENTWORTH, A. R., assistant surgeon. Ordered to temporary duty, Navy Yard, League Island and Pennsylvania.

LIPPINCOTT, G. C., past assistant surgeon. Ordered to Annapolis, Md., for temporary duty, member Medical Examining Board.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE HOSPITAL SERVICE FOR THE WEEK ENDING AUGUST 14, 1886.

CARTER, H. R., passed assistant surgeon. Granted leave of absence for thirty days, August 12, 1886.

GLENNAN, A. H., assistant surgeon. Granted leave of absence for thirty days, August 9, 1886. To examination for promotion, August 12, 1886.

BETTUS, W. J., assistant surgeon. When relieved at Savannah, Ga., to rejoin station, New Orleans, August 13, 1886.

IN MEMORY OF FRANK HASTINGS HAMILTON.

At the meeting of the Chicago Medical Society, held August 16, 1886, the annexed preambles and resolutions were unanimously adopted:

Whereas, This Society has learned with deep regret of the death of Dr. Frank Hastings Hamilton, of New York, and,

Whereas, In his death the United States has lost one of its most distinguished surgeons, one of its ablest teachers, one of the purest patriots, and in his private life, one of the most amiable men.

Therefore, be it resolved by this Society, that we hereby give public testimonial to the many virtues of the deceased, and that we tender his family the assurance of the profound sympathy of this Society with them in the hour of their affliction, and that an *engrossed* copy of these resolutions be furnished them, and a copy spread upon the records.

BOOKS AND PAMPHLETS RECEIVED.

Twenty-Seventh Annual Announcement and Catalogue of the Hahnemann Medical College and Hospital of Chicago, Ill., 1886–87.

Fifth Annual Announcement and Catalogue of the Womans' Medical College of Baltimore. For the Session 1886–87. With an alphabetical list of all the graduates of the college. Baltimore, 1886.

Erysipelas and other Septic and Infectious Diseases Incident to Injuries and Surgical Operations prevented by a Method of Atmospheric Purification (Second Presentation.) With an Original and New Wood-cut, and with a Report of Cases of Laparotomy. By David Prince, M.D., of Jacksonville, Ill. Second Edition. (From the American Practitioner and News for April 3d and 17th, 1886.)

Annual Announcement of the Buffalo College of Pharmacy. Department of Pharmacy, University of Buffalo. For the Session of 1886–87.

Arabic and Hebrew in Anatomy. By F. B. Stephenson, M. D., United States Navy. (Reprinted from New York Medical Journal for July 24, 1886.)

AN EPIDEMIC OF MALARIA IN EASTERN MASSACHUSETTS.[1]

BY ZABDIEL B. ADAMS, M.D., OF FRAMINGHAM.

Of the various theories of the nature of the disease, that of Professor Cantani, of Naples, seems the most complete, if not the most satisfactory, of any. It is, that "the malarial infection depends upon a parasite (once supposed to belong to the family of algæ.) Tomasso Crudeli, Klebs, and especially Marchiafava,[2] claim to have demonstrated the existence of a malarial microbe. It enters into the blood probably more readily by way of the digestive tract than by the respiratory organs. Unquestionably water is the surest vehicle of the infection, and drinking-water is the source from which arise the worst forms of the malady. No other mode of introduction gives such severe infection. It is quite uncertain if it ever enters by the air alone."

However it may enter the blood, the micro-organism finds its way to the spleen, which, under the stimulus of its presence, undergoes a disturbance of its nutrition and becomes enlarged.

In a person with normal spleen and healthy elastic capsule, the germs, entering this organ and multiplying in it, stimulate it until its contractile elements excited to action expel the blood into the general circulation, carrying with its stream the microbes which have collected. The reaction of the organism under the excitement of the presence of this ferment in the blood, produces chill, fever, and sweating. With the fever the germs are destroyed or are eliminated, and thus the access is ended. Then there is a pause, during which the germs may rapidly multiply and again excite the spleen to contract, or there is a stage of relaxation and rest, while the multiplication of the germs goes on until the exhausted spleen recovers its contracility again, and we have another expulsion of its contained blood, and another access of fever.

If the spleen is healthy and capsule elastic, this may be repeated every day, the power of contraction being quickly restored; or with a less degree of sensibility we may have an interval of forty-eight or seventy-two hours.

It follows that the more perfect the sensibility of the spleen the shorter the intervals of rest; and in the quartan form, which is the most obstinate and rebellious, the stimuli become more powerful in their phlogogenic elements.

Thus the enlargement of the spleen in the chronic form of malaria is explained. In this form certain stimuli which act upon the liver may awaken the torpid contractile elements of the spleen, and produce fever. Thus, in those suffering with chronic enlargements, mountain air may cause an access. Certain errors in diet may do the same, especially the abuse of certain fruits; and it is suggested in this connection that some vegetables that ripen upon the ground, such as melons, may give rise to malaria by introducing the germs directly into the intestinal tract. The fever is perhaps the reaction of the body against an enemy which threatens life. An access of fever is fatal, as is well known, to many of the micro-organisms (witness the spirilli of recurrent fever). The fever is in this view a beneficient act of nature.[3] This is the theory of Prof. Cantani.

All the phenomena of the attack point distinctly to a nervous origin. A man in apparent health suddenly has a chill. His fingers and toes turn blue and cold, and shrink as if parboiled. The whole surface has a dusky hue. He complains of headache, is sick at his stomach, and perhaps vomits. He cannot sustain himself, and lies down. Suddenly he is convulsed with a shudder so profound as to shake the bed, the room, and the whole house. The external application of heat gives no relief. While the surface is chilled the internal parts become hot. This goes on for an hour, two hours, perhaps longer. Here is every indication of vaso-motor disturbance or irritation, resulting in driving the current of blood upon the internal organs. Then follows a burning fever. The temperature mounts. The face becomes flushed, headache more violent, thirst intense, and great restlessness. The theory is pretty generally accepted that *fever* is due to some irritation of the nerve centres of heat in the medulla or in the spinal cord. Dr. W. M. Ord, in an address before the London Medical Society last year, gave a striking and ingenious explanation of the origin of pyrexia. In the process of growth, he says, heat disappears. This Dr. Ord demonstrated to his own satisfaction in a growing cucumber. Whenever the constructive processes are arrested or disturbed, heat is set free. In the destructive changes in the body it is known that heat is generated. Fever follows, therefore, whenever nervous force enters to disturb or interfere with the *constructive*, and also to increase the *destructive*, metabolic processes. The sweating stage must be dependent upon the same cause as the preceding chill and fever.

But the intermission, the sudden and complete cessation of all symptoms, almost compels the conclusion that the phenomena are of nervous origin.

Then with regard to the spleen. Experiments by vivisection have shown that the spleen is capable of undergoing great modifications in size by irritants applied to the medulla.[4]

Paralyzing, or inhibiting, the splanchnic nerves caused the spleen to dilate. The volume of the spleen, of course, corresponds to the amount of blood it contains. The malarial infection may, either directly, or by acting as a ferment in the blood supplied to the part, or by stimulation even of the peripheral extremities of nerves, so irritate the medulla as to cause the spleen to dilate by reason of inhibition or paralysis of its nerves. The paralysis ceases and the spleen resumes its normal size, expelling the excess of blood.

This view does not, perhaps, differ irreconcilably from that of Prof. Cantani, as given above.

The modern views of the origin of disease, and especially the germ theory, compel us to recast our ideas of the etiology of intermittent fever.

Until a comparatively recent date it was considered, in spite of much contradictory evidence and some vague theories, that the origin of malaria in any locality was sufficiently explained, if heat, moisture, and vegetable decay, were present and active at the same time.

Now, however, there are found writers on the sub-

[1] Concluded from page 176.

[2] Prof. Cantani, by thus discriminating, would imply that the claim of Crudeli and Klebs are no longer urged. Vide page 22.

[3] Medical Clinic, Hospital Gesu e Maria Monthly Supplement, Gazetta degli Ospitali, Naples, June, 1885.

[4] Ziemssen's Cyclop., vol. viii. p. 364.

ject who do not hesitate to deny any and all agency of these factors in the production of intermittents.

The worst possible sanitary conditions cannot produce an epidemic of small-pox, nor can

> "All the infections that the sun sucks up
> From frogs, fens, flats," ——

generate a single case of intermittent fever; but the germs of these diseases being present, who will deny that the small-pox flourishes best in badly-ventilated houses and where people are filthy, or that malaria will show itself in greatest intensity in the vicinity of swamps and stagnant water.

The study of bacteriology is still in its infancy. The method of investigation seems thus far to have followed only one direction. The cultures are made under conditions similar to those which exist within the animal economy, the germs being developed and studied under the microscope in connection with organic substances, generally animal, acting with heat and moisture.

But is it not clear that there must be modes of being, and probably stages of development, apart from the living animal body, and not dependent upon its blood-globules or albuminoids? Here is a part of the natural history of the microbe which requires notice. Unless we are willing to admit that they may be bred autochthonously, we cannot escape the conclusion that the germs are in existence during the epidemic intervals. Some, it is true, may continue their growth in other organisms, animal or vegetable; but it is a matter of belief that some survive in the graves of the dead, some exist in wearing apparel, or houses, some in dust, and some again in water or floating in the atmosphere.

What causes the microbe to develop into activity at the time of epidemics is a curious and important question. All of them doubtless obey a law of *periodicity*. There is a time of rest when the germ or spore remains neutral and harmless, and again, the conditions being favorable, it develops into virulence. There is, however, in the human organism at the epidemic period some unknown receptivity awakened, when, probably by the law of natural selection, the germ received into the body produces the disease. But must we not admit also this *active state of the germ* at the time of epidemic outbreak?

If those views are correct, two agencies combine to cause an epidemic: first, the presence of germs in a state of active growth, and secondly, a condition of the human body which determines the natural selection. It is probable that neither of these could produce the effect alone, but that both must act together. Hence the statement that zymotic diseases are maintained and spread solely by the contagious principle or germ, and "*that there are no other causes in operation*," requires modification, since, besides a state of the body rendering it receptive, some condition, possibly telluric, must exist which awakes the morbific power of the free microbe.

With regard to the germ of malaria we may infer that we know something of its natural history in its free state, and apart from the pathological phonomena which it gives rise to. First, it is bred into activity by heat, vegetable decay, and moisture, in conjunction, probably, with light and air, and thus resembles organic life in general. Then it has weight and size, since it falls to the ground, is blown about by the wind, and arrested by obstacles. It requires stagnant water for its growth; it cannot live in running streams, nor in large bodies of moving water. It is destroyed by drainage and cultivation of the soil, and is stifled or rendered inert by being covered in as in buildings, and per contra it is liberated by opening up the ground. It is carried to and fro by fog and mist, and very likely by clouds and rain. These facts are not beyond question, but they are attested by countless observers in all countries.

On the other hand we know very little about the history of other disease germs except in cultures. And what do we learn from these? The distinction somewhat insisted upon by bacteriologists between saprophytic and pathogenic germs is not important in this connection, the object being to determine how these things develop when removed from all influence of organic fluids or solids. Equally useless to this investigation are efforts like those of Vogel to harmonize the processes of disease with those of fermentation by artificial methods.

Pleomorphism is the rule, and distinct morphological characters do not indicate necessarily specific differences, which are to be sought in the whole life-history of the microbe. Dr. J. S. Billings says, "as we cultivate bacteria in different media we find a change in their form. It is possible that they may gradually change by alteration of the medium, of its chemical composition, or of its temperature." In artificial cultures in twenty-four hours the cocci are seen to have become rods, in forty-eight hours cocci-chains, in fourteen days zoogloea. Cocci transplanted again become rods. From the fusion of two cells arise, in another case, a host of potential cells each having all the powers of original cells, which powers seem to reside in the nucleus, — "this cell nucleus possessing inherent properties which make it the one essential constituent of the cell itself."

We may assume, without much fear of contradiction, that the free germ or spore or nucleus (as the case may be) exists for an indefinite period in a dry, or at least an inert, state. Further than that we believe that some are made active by contact with filth, some by moisture, others again by heat, or by all of these combined. But beyond this we must wait for the investigations of those who are making this subject a special study. Dr. E. W. Cushing[5] has found that the balcillus tuberculosis cannot live in cultures at a temperature below 85° F. And yet there must be some mode or state of being of these organisms apart from the living animal body.

Looked at in this light may we not conclude that the malarial germ in its free state is more highly organized than other microbes? In a general way the statement may be hazarded that the malarial germ does not require the agency of the animal body for its development, whereas we can scarcely point to a fact in the natural history of other microbes proving their free and independent existence.

The pathological phenomena also indicate important distinctions between malarial germs and those of the zymoses, especially. In the first place malaria never, it is believed, acts by infection or contagion. The germ escapes from the body in an inert or harmless state. While it is the rule in zymotic diseases that the germ acquires increased virulence by residence within the body (at least until the "epidemic

[5] And others.

constitution," as it is called, has been exhausted), the malarial microbe, like the Giant Antæus, born of Neptune and of the Earth, expires, if its strength be not renewed by a return to the water and to the soil. Malaria, therefore, thrives in the open country, while zymotic diseases spread chiefly in cities.

Another frequent rule is that the receptivity of the body, its power of natural selection is destroyed or diminished by the agency of the germ, a first attack preventing a second. Not only is this not true of intermittent fever or malaria, but it may be doubted if natural selection plays a very important rôle in the etiology of its epidemics, unless the fact of a periodicity in all diseases appearing before an outbreak of malaria be cited in proof of this.

Why malaria spares the colored races which are so especially prone to attacks of infectious and contagious diseases, is a question which awaits further inquiry.[6]

In 1849, Professor J. K. Mitchell, of Philadelphia, in a paper "on the cryptogamous origin of malarious and epidemic fevers," suggested a direction for the study of the etiology similar to that intended in this paper. His theory was admitted to be in harmony with the fact, but was never sustained by actual demonstration.

In 1866, it will be remembered that Dr. J. N. Salisbury declared that he had discovered the origin of malaria in the minute spores of certain species of palmellæ, which he found in great numbers in the saliva of those suffering from intermittent fever, and also in or upon marsh mud recently dried.

Others have followed in the same track without greater success. The spores or ovules of various cryptogamous organisms have been suspected. In all cases, however, it could be shown that these minute plants throve abundantly in non-malarious regions, and indeed wherever light and moisture were present. These plants cannot therefore furnish the germ, or essential factor, for which search is to be made.

What of the contagion vivum? Prof. Marchiafava and Dr. Celli claim to have discovered in the interior of the red corpuscles of the blood, in those suffering from malarial fever, minute organisms having amœboid movements, and which can be distinctly stained. These they term pla-modes of malaria. They are capable of transformation, by a process of fission, into granules not possessing motion. As infection progresses these bodies multiply, and are accompanied by an accumulation of pigment. The exhibition of quinine causes them to disappear or deprives them of all motion. They diminish as infection ceases. The intravenus injection of malarial blood will cause them to appear and multiply in the blood of the recipient. They are regarded as of a parasitic nature, and as belonging to the simplest class of protozoa. "As yet their pure culture outside of the body has not been effected, nor their natural source discovered." (*Bos. Med. and Surg. Jour.*)

The effect has been made in this paper, while covering the ground of what is believed to be known with regard to the malarial infection, to draw as near as possible to the borders of its "boggy Syrtis," and by the aid of the germ theory to throw light into the fog and mists which now shroud it from view.

[6] That an acquired melanosis of malarial origin, or that the protection against insect bites afforded by a dark skin, should be accepted as a sufficient explanation of the exemption of the colored races from malaria, seems to the writer to be not consistent with the facts, and not sustained by authority.

It may not be too much to claim, in conclusion—*First*, that water is almost certain to prove to be its habitat, and the vehicle by which this microbe enters the human organism; *Second*, that by new methods of investigation its life-history may be studied; and *Third*, these two points being gained, that it is possible to attack the free germ, or prevent its admission to the body and thus the disease may be checked.

In the future undoubtedly new devices will be employed for the prevention of epidemic diseases. Thus far the only effectual method has been that introduced by Jenner and vaccination, namely, the exhaustion of the "epidemic constitution" in the human being. In most of the zymoses this factor is first in importance. But to prevent the development of epidemic virulence in the free microbe is probably in certain diseases of equal, if not of greater, necessity. In malaria, for example, may not this parasite be found and destroyed in its dormant, chrysalid, or nascent, state? May it not be sought and studied in water better than in the animal fluids? And, if this be admitted, there seems no clear and sufficient reason why our other senses, smell, taste, perhaps touch, aided by chemistry, it may be, or possibly electricity or mechanical means, should not, in this simple element, help us in accomplishing that which, in the case of bacteria and bacilli, is only possible to the organ of sight assisted by the microscope.

ABDOMINAL CELLULITIS.[1]

BY JULIAN A. MEAD, M.D., OF WATERTOWN.

The term abdominal cellulitis does not appear in the index of any medical work that I have consulted; and its analogue, pelvic cellulitis, is fast yielding to the influence of the modern analytical tendency, which divides and sub-divides each subject until the broad and distinguishing characteristics of the whole are overshadowed by the peculiarities of the part.

Without the least desire to call in question the great gain that this classification has conferred upon our profession, it has seemed to me that something perhaps may be learned by imitating the microscopist, who, by occasionally substituting the lower power for the high, obtains a more comprehensive, if less minute, idea of the nature of the pathological condition under examination.

The abdominal cavity contains a large amount of what is known as cellular or areolar tissue. It surrounds and supports the various organs, and is distributed so universally throughout the abdominal cavity, that it is necessarily concerned in most inflammations, and is the seat of the chief changes that result.

The areolar tissue consists of loosely-interlaced bundles of two forms of fibrous tissue, the white and yellow, with flattened connective tissue corpuscles adherent to them, together with a great quantity of capillary vessels, nerves, and lymphatics, and, in most places, fat.

According to Gray, the chief use of the cellular tissue is to bind parts together; while, by the laxity of the fibres and the permeability of its areolæ, it allows them to move on each other, and affords a ready exit for inflammatory and other effused fluids.

This tissue, when inflamed, whether in the abdomen

[1] Read at the Annual Meeting of the Massachusetts Medical Society, June 8, 1886, and recommended for publication by the Society.

or elsewhere, undergoes important changes. The essential changes that take place in inflammation have been satisfactorily demonstrated; the difference in the symptoms depends largely on the seat and intensity of the inflammation, and their variability is not a valid argument against the unity of the process.

The credit of the modern explanation of inflammation belongs to Cohnheim; it matters not whether or no we admit that a proliferation of the fixed corpuscles takes place, as is held by Virchow, Von Becklinhamen, and Stricher; the only satisfactory explanation of the phenomenon of inflammation is that afforded by Cohnheim's theory. As observed and stated by Cohnheim, the changes in an inflamed tissue are as follows: The vessels, in the order of artery, capillary and vein, at once begin to increase in size, the velocity of the blood, at first quickened, gradually diminishes, and the white corpuscles range themselves along the walls of the veins, where they move slowly along, tumbling over each other until they become stationary. On the outer contour of the walls of a vessel, usually a vein, in which the marginal layers of white corpuscles are well developed, is seen a small projection, which enlarges in length and breadth, and becomes a rounded, colorless lump. This again enlarges, puts out new pointed projections, and gradually withdraws itself from the wall of the vessel until it is attached to it only by a long, narrow stem. Finally this attachment is broken, and we see a colorless, contractile body, with one long and several shorter processes, with one or several nuclei, in fact, a white corpuscle. The white corpuscle in this way passes out of the vessel and becomes a foreign body. The number of corpuscles that pass through a vein in a certain time depends upon the intensity of the inflammation; when, however, the inflammation is fairly acute, six to eight hours suffice to completely surround the veins and capillaries. Red corpuscles also pass through the walls of the veins and capillaries, but neither white nor red pass through the walls of the arteries. The liquor sanguinis soon follows, and the surrounding tissue is soon drenched with it.

The cardinal symptoms of inflammation, heat, pain, redness, and swelling are readily understood and explained, if we bear in mind the above-mentioned minute changes that take place in the vessels. The swelling, heat, and redness are the direct result of the effused corpuscles and liquor sanguinis. The pain is caused by injury to, or pressure of the nerves. The fifth symptom, impairment of function, is accounted for by the size of the exudation, and the lack of the usual nourishment.

Such an inflammation of the cellular tissue cannot occur without causing injury, the extent of which is proportional to the nature of the cause of the inflammation, and the degree to which its harmful influence is felt.

Inflammation ends in resolution, production, or destruction. By resolution is meant complete absorption of the exudation, and restoration of the integrity of the affected part. This process begins as soon as the walls of the bloodvessels are restored to their normal condition. If the inflammation is mild, and the injury of the bloodvessels trivial, the cellular tissue is quickly relieved of the exudation, which is taken up, partly by the lymph-vessels and partly by the bloodvessels. Should the inflammation be more intense and cause considerable exudation, and a slight destruction of the tissue, the process of resolution is more complicated; the fluid part of the exudation and the cells are absorbed as before, but the solid part of the exudation must become softened and liquefied before the lymph and bloodvessels can take it away. This dead tissue, removed by the vessels, is, if not large in amount, replaced by a new and similar growth. Sometimes, indeed, the amount of this regenerative growth exceeds the original loss, and causes a hyperplasia of the diseased tissue.

Inflammation ends in production when the process is more intense than that which results in resolution, but not sufficiently intense to induce the formation of pus, and also when the circulation in the bloodvessel is not materially impaired. According to Ziegler, the cells that form this new productive tissue, granulation or cicatricial, are the same white corpuscles that have passed out of the vessels.

The essential part of the formation of this new tissue is the existence of new bloodvessels, without which the tissue would not be produced or sufficiently nourished. Unfortunately, all inflammations do not run the favorable course above described. Instead of resolution and production, there may be destruction. This happens when the nutrition of the inflamed tissue is cut off by the stoppage of the vessels on which the tissue depends for its support. The more abundant and more cellular the exudation, the more likely is the inflammation to end in destruction. Billroth says, as the inflammation progresses, the entire inflamed part is finally changed to pus, that is, to fluid tissue, consisting of cells with some serous intercellular fluid, which is mixed with shreds of dead tissue. The tissue surrounding the purulent collection is filled with cells, and is very vascular; anatomically, it closely resembles a granulating surface lining the whole cavity.

If the exudation softens and becomes liquid rapidly, it forms an acute abscess; if slowly, a cold abscess. The course of inflammation has been described somewhat in detail, because it will assist to a more intelligent understanding of the nature of the inflammatory process that takes place in the cellular tissue of the abdominal cavity. This pathological change is practically the same, whether the seat of the disease be near the cæcum or kidney, in the abdominal wall, or in the fascia behind the peritoneum. Its course and its results may be, and undoubtedly are influenced by the surroundings, but the inflammation goes steadily on to resolution, production, or destruction, with the formation of pus.

As in diseases of the kidney it is not uncommon to find one type complicated by another, and the most important symptoms obscured by the prominence of the complication, so we shall find that an inflammatory process of the cellular tissue does not in every case run a typical course. The symptoms will show that complications exist which, while they do not change the nature of the disease, modify its course and influence its manifestations.

It is generally admitted that an abscess which originates in the abdominal wall, in the sub-peritoneal cellular tissue or in the region of the loins, and is totally unconnected with disease of bone, or with ulceration of the bowels or with child-birth, is not a very common occurrence.

Dr. Gurdon Buck says that suppuration may take place in the iliac fossa behind its fascia, unconnected with caries of the lumbar vertebræ or pelvis or morbid lesion of the cæcum or colon. The same writer describes the true postfascial abscess originating in the

iliac fossa from idiopathic inflammation of the cellular tissue, as follows: It represents itself in a chronic, more rarely in an acute, form, and locates itself in either the right or left iliac region. It is most frequent in adult age. The tumor which it forms rises up from the hollow of the ilium, pushing before it the fascia and outer half of Poupart's ligament so that the crest of the ilium and the anterior superior spinous process can no longer be grasped between the thumb and finger. The outer half of Poupart's ligament, is rendered tense and unyielding, and a deep seated induration may extend two or three fingers' breadth below it. The precise limits of the swelling can only be appreciated by the touch and by percussion over its abdominal portion; upon the surface, the eye perceives only a fulness or a diffuse swelling of those parts.

Of seven cases, in only one was fluctuation unequivocal. In all except one the thigh was retracted and attempts to straighten it caused pain.

The phlegmonous character of the swelling, its anatomical relation to the iliac fossa and Poupart's ligament, the absence of disease of the lumbar vertebræ and the co-existing retraction of the thigh, these points being clearly made out, are sufficient to warrant the conclusion that suppuration has taken place in the fossa behind the fascia.

Oppolzer divided the inflammatory process in the region of the cæcum into perityphlitis and paratyphlitis, the former being limited to the peritoneal envelop of the cæcum and appedix vermiformis, and the latter to the post-peritoneal and post-cæcal connective tissue. This is a refinement in diagnosis that is not warranted by actual experience. A preponderance of certain symptoms, namely, the pressure symptom in the right lower extremity; the flexed thigh; formication, numbness, pain, and sometimes paresis of the right leg; dysuria, and retraction of the testicle, and pressure upon the iliac vein inducing trombosis, show that the tissue behind the cæcum has become affected, but these symptoms do not limit the disease to this locality. In a majority of cases the peritoneal covering of the cæcum and the vermiform appendix participates in the inflammation. An English writer says that there is reason to believe that this malady is often passed over unrecognized, and is of more frequent occurrence than is supposed. This is said to be the case in children, in whom cases of iliac abscess around the cæcum are liable to be mistaken for hip-joint disease, though with perhaps scarcely sufficient reason.

This disease is generally secondary to some affection of the cæcum, but also arises from perinephritic and psoas abscess, vertebral caries, septicæmia, and external injuries such as blows, kicks, or severe compression.

In the admirable "Letters to a Young Physician," by Dr. James Jackson, mention is made of a painful tumor near the cæcum. Dr. Jackson located the pain and tumor on a horizontal line connecting the two anterior superior spinous processes of the ilium at the point where this line intersects the right margin of the rectus muscle on the right side. This tumor is felt on deep percussion. Sometimes it is superficial. Marked tenderness on pressure exists within a circumscribed space over the tumor. According to Virchow, the tumor may be as large as a man's fist, but as a rule it is much smaller. Dr. Jackson frankly admits his inability to form an opinion as to the precise seat and nature of this affection. It is clear, however, that he described what is known as perityphlitis, that is an inflammation of the connective tissue around and behind the cæcum; the accuracy of his localization and description is borne out by modern research.

The nature of this affection has been described in the beginning of this paper, and an intelligent explanation given of the swelling, pain and nervous symptoms. The gradual disappearance of the tumor in one case, and the formation of an abscess in another, was accounted for. The same treatment, namely, rest, poultices, opium, and an early opening of the abscess, that has been found beneficial in inflammations in other localities, is indicated here for the same reason. Opium and incision of the abscess should be resorted to early, on account of the danger of rupture into the peritoneal cavity. The value of opening these abscesses is shown by contrasting the sixty-seven cases, mostly treated without incision, with a mortality of forty-seven and a half per cent., reported by Bull, of New York, in 1872, with the one hundred cases treated by operation, with a mortality of only fifteen per cent., reported by Noyes, of Providence, in 1883.

Another favorite seat for abdominal cellulitis is the loose connective tissue around and behind the kidneys. This affection has received the name, from its location, perinephritis. The inflammatory process generally begins in the connective tissue behind the kidney. Perinephritis, like perityphlitis, is generally secondary, but it may be primary.

In the earlier stage the cellular tissue behind the kidney is suggested; later, as a result of the exudation of the white corpuscles and liquor sanguinis, it becomes solid and firm. This congestion causes from the first pain and tenderness. When exudation has taken place, a hard tumor appears in the lumbar region which, if the inflammatory process continues, becomes soft and fluctuating in the middle, and generally more distinct and superficial.

The inflammatory process may stop short of the formation of pus, and the swelling may gradually disappear. The inflammation is then said to have terminated in resolution. Trousseau in his Clinical Medicine mentions several cases that resulted in this way. If the inflammation goes on to suppuration the tumor should be explored, and the pus, when demonstrated, should be at once removed. An early incision is desirable, as it may anticipate an unfavorable burrowing or pointing of the abscess.

Local inflammation of the cellular tissue may occur in the abdominal walls unconnected with disease within the cavity, and may terminate in suppuration. Such abscesses are generally the result of an injury, and are usually found near the umbilicus. The absence of urgent symptoms referable to the abdomen will distinguish these abscesses from the peritoneal abscess. An effort on the part of the patient that makes the recti muscles tense, such as raising the trunk or forced expiration, will protrude the superficial and obscure the deeper tumor. These abscesses require but little treatment, and the prognosis is generally good. In case they are connected with and dependent upon some intestinal trouble, the progress and treatment depends on the extent and nature of the intestinal disease. Dr. Howell, of England, reported a case of a man with a small, hard tumor, about the size of a hen's egg, lying over Poupart's ligament, about midway between the external and

internal abdominal rings. After two days the tumor began to soften, and an incision was made and four ounces of pus were discharged. On the following morning two worms were found in the poultice. Fæces passed by the wound for three weeks. The man recovered within two months. After confinement it is not uncommon to find an extra-peritoneal abscess in the inguinal region. To quote Dr. Coale, its most frequent seat is where the aponeurotic covering of the deep abdominal muscles going to the thigh passes into the fascia transversalis and Pourpart's ligament. Examination by the rectum and vagina rarely affords any information. In course of time the abscess extends upwards towards the inguinal region, where its presence soon becomes manifest. Here, as in other cases of abscess, an incision should be made as soon as its situation is obtained, and the pus removed.

The foregoing are some of the favorite seats of abdominal cellulitis. The experience of the members of this Society will prove that the list has not been exhausted. Perhaps some of those tumors of the abdomen whose character is obscure, and which do not belong to the so-called phantom tumors, nor to that class that disappear after a good cathartic, may be examples of inflammation of the cellular tissue of the abdominal cavity. It is certain *a priori* that a tumor may appear wherever there is cellular tissue, and an exciting cause for inflammation, and that, while the physician, somewhat in doubt as to the nature of the swelling, postpones aspirating, it may by the process known as resolution, gradually disappear. Such a tumor, when the result of chronic inflammation, might simulate a malignant growth, and suggest a prognosis entirely unwarranted by the nature of the case and its subsequent course. If the pathological condition is recognized, and the changes in the inflamed tissue understood, the prognosis becomes more certain, and the treatment more effective. Should the tumor tend to resolution, general treatment, together with morphia to relieve pain, and poultices to assist the resolution, will suffice. But when pus is suspected or actually demonstrated, an effort should be made at once to remove it, either by aspiration or incision.

The object sought in the preparation of this paper has been to call attention to the frequency of abdominal cellulitis; in short, the unity of its course in different parts of the abdomen; to suggest the possibility of mistaking for other diseases; to explain the nature of the disease, and to point out the necessity of an early evacuation of the pus.

— A correspondent of the *Medical Brief* states that Mr. Savory, President of the Royal College of Surgeons, was recently going round his wards at St. Bartholomew's Hospital, when he came to a case of hernia just operated upon. Turning to one of the students following him, he asked: "You have passed, have you not?" An affirmative answer was returned. "What is a good thing after an operation for hernia?" "A dose of opium." "How much would you give?" "Ten grains." "How would you give it?" "The liquid extract." How much of it would you require to give you ten grains of opium?" "Half a drachm." "They will not be long before they require an extra coroner in the district where you settle down," was his comment.

BACKWARD DISLOCATION OF THE FINGERS UPON THE METACARPUS.[1]

BY E. O. OTIS, M.D., OF BOSTON.

Two cases of backward dislocation of the index finger upon the metacarpal bone give me the text of my subject. One refused to allow a proper attempt at reduction on account of the pain, was unwilling to take ether, and can be speedily dismissed.

The other, a student, was practising jumping for an athletic tournament, and fell upon his hand, with fingers extended. He and his companions noticed at once the deformity, and tried to pull the finger into place. Failing in this, he appeared with his friends at my office. I attempted, by the "Crosby Method" — to be described later, and which was first brought to my notice several years ago by Dr. William Ingalls — to reduce it. Not succeeding, I gave him ether and renewed my attempts, but unsuccessfully. I then rested a while, long enough to have made a Levis's apparatus, which, when applied, gives one an artificially lengthened finger by which greater force can be used in extension. Then, again administering ether, I made a careful and prolonged attempt to reduce the luxation. Several times I thought this was accomplished, but the joint, being left to itself, the dislocation always recurred. Finally, I desisted, and allowed the boy to come out of ether. I then told him that the only thing to be done was an operation; an incision of some ligament or ligaments, having a very vague idea myself of exactly what was to be done. His home being not far distant, I advised him to see his parents and family physician and explain to them what I desired to do, and obtain their consent. He went home, and I did not see him again for some weeks. His finger then did not seem to be in place, nor had it regained its original freedom of motion, although he told me his family physician had performed some sort of an operation. This is the last I saw of him, and the ultimate result I do not know. The case, however, left a very vivid impression upon my mind of the possible difficulties in the reduction of a dislocated finger, quite different from that one would obtain from Keetley's single sentence upon the subject: "Dislocation of fingers," he says, "are not common, and may be reduced by extension."

Since, as Billroth says in discussing dislocations, "Everything depends on correct anatomical knowledge," I shall first consider the *Anatomy of the Metacarpo-phalangeal* joint, next the *pathology* of the injury, and finally, the *treatment*, based upon the previous considerations. I shall, moreover, refer often to dislocations of the thumb in considering those of the fingers, for the two injuries are anatomically and pathologically in many respects quite alike. I shall make frequent reference to Jalaguier's recent and admirable article on the subject in the *Archives Générales de Médecine* for February, 1886.

The metacarpo-phalangeal joint is an enarthrodial one (Tillaux), characterized by the reception of a head into a cavity, the cavity being much smaller than the head which it contains. The size of the cavity, however, is much increased by the anterior or glenoid (Cruveilhier) ligament. This ligament is thick, dense and fibro-cartilaginous in texture; placed on the palmar surface of the joint, inseparably connected with

[1] Read at the meeting of the Boston Society for Medical Observation, May 3d, 1886.

the phalanx where it is thick and strong, but only loosely united to the neck of the metacarpal bone where it is thin and delicate (x Fig. I. Schüller.)

Fig. I.

The glenoid ligaments of the index and middle fingers sometimes contain a sesamoid bone. Constantly, in the index finger, according to M.M. Jalaguier and Polaillon, while two always exist in that of the thumb. There are two powerful lateral ligaments united one with another by the glenoid, and forming thus a continuous band from side to side. The glenoid ligaments are connected one with another by the transverse ligament of the metacarpal bone, which is a narrow fibrous band. The extensor tendon takes the place of a dorsal or posterior ligament according to Gray. Kelly,[2] however, says, with reference to the thumb, that the posterior ligament is a strong, independent structure, perfectly distinct from the dorsal tendons and their expansions, from which it is separated by a bursa.

The mechanism of flexion and extension is as follows, after Jalaguier: In flexion the phalanx glides over the head of the metacarpal bone through an arc of ninety degrees. The glenoid ligament is relaxed as well as the fibres of the lateral ligaments which are attached to its sides, while the phalangeal part of the latter ligaments, on the contrary, is put upon the stretch, and limits the movement of flexion.

In extension the phalanx glides from before backwards upon the head of the metacarpal bone, which, in extreme extension, almost entirely corresponds to the glenoid ligament, which becomes more and more stretched along with the glenoid fibres of the lateral ligaments. The tendon of the flexors and transverse ligament also contribute to limit extension.

If now extension is exaggerated violently, a rupture is produced at the weakest point, which is at the metacarpal attachment of the glenoid ligament (x Fig. I). In a hundred trials upon the corresponding joint in the thumb, M. Farabeuf found that the phalangeal insertion of this ligament was not once ruptured. Schüller[3] also says, in reference to the same joint, that the palmar capsule, as he calls this ligament, regularly ruptures at its metacarpal insertion in backward dislocations. In my limited experiments upon the cadaver (through the kindness of Professor Dwight and of Drs. Newell and Conant) the glenoid ligament was always ruptured at its metacarpal attachment in case of the fingers. With the thumb, however, the sesamoid bones seemed to make a difference, and in the few experiments tried, the ligament was ruptured nearer its centre; once directly through the sesamoid bones.

It is upon this pathological fact — the rupture of the glenoid ligament and its place of rupture — that all procedures for reduction must be based, and from ignorance of it that all the trouble from wrong procedures has arisen, just as in the case of the hip joint before Bigelow discovered the part played by the Y ligament. Indeed, there is quite a striking analogy in the case of the two joints in the matter of ignorance of the exact cause of the dislocation, and consequently of wrong procedures in the reduction. In attempts to reduce the hip by extension alone, the femur has been fractured, and irreparable injury done. In attempts to reduce the first phalanx by extension alone, it has been torn off, according to Hey.

The glenoid ligament, being ruptured then at the point named, the head of the metacarpal bone escapes through the rent, and the phalanx, with the torn ligament hanging to it, ascends the dorsum of the metacarpal bone. At the same time, also, the anterior fibres of the lateral ligament are torn, though Schüller says these are not necessarily ruptured. In my own experiments, it seemed necessary that these ligaments should be more or less ruptured in order that the head of the metacarpal bone should escape entirely through the rent

Having, then, a complete dislocation, the disposition of the parts is as follows for the index finger, according to Jalaguier. The phalanx rests by the anterior part of its articular face, upon the neck or dorsal surface of the metacarpal bone (Fig. II). It is held there by the flexor tendon, deviated within by the extensor tendon, which raises the skin, and by the remnants of the lateral ligaments. The glenoid ligament, which has followed the phalanx, is in contact with the head and dorsal surface of the metacarpal bone (Fig. II). Its palmar surface has become dorsal, and corresponds to the anterior face of the dislocated phalanx, with which it forms an angle with its apex above; open if one apply dorsal flexion, and closed by palmar flexion. Its articular face rests upon the neck, or even upon the dorsum of the metacarpal bone (Fig. II).

Fig. II.

Such being the disposition, the glenoid ligament must be brought into its place, and this can only be done by using the phalanx as a lever, and pushing before it the ligament which followed it in the act of dislocation.

The technique of the procedure is as follows: Carry back the phalanx in forced extension, keeping its base closely applied to the dorsum of the metacarpal bone. Then slide its articular surface upon the dorsum of the firmly-fixed metacarpal bone until it reaches the head of the latter, and finally flex the phalanx, when reduction ensues. All attempts at extension in a straight or flexed position, although they may be followed with success, offer the risk of making the dislocation irreducible, and are based upon a wrong conception of the part played by the glenoid ligament.

This is called the Roser or dorsal-flexion method, and also in this country, the Crosby method. Dr. Cutter quotes Dr. Crosby as saying in his lectures — "that he had never failed in the few cases which had occurred in his practice, although, in several instances, all other methods usually adopted had been tried without effect." Dr. Cutter, in the *Boston Medical and Surgical Journal* for 1857, Vol. XVII, p. 172, gives so admirably his procedure with this method, in case of the thumb, that I will reproduce it here: — "I placed the patient," he says, "in a common chair, and took a seat in another at his side, both of us facing the same way. An assistant sat behind us to hold the patient's elbow fixed. I then took hold of the metacarpal bone with my right hand, my forefinger passing between his thumb and forefinger, and my thumb resting on the top of the metacarpal bone, with the end touching the dislocated end of the phalanx. With my left hand I tipped

[2] Notes on Dislocations of the Thumb, reprinted from Dublin Journal of Medical Sciences, May, 1883.
[3] Chirurgische Anatomie, part I, 1885.

the phalanx back until it stood perpendicularly on the metacarpal bone; then pressing the phalanx forward by the end of my right thumb, it was readily carried by flexion into place, and the joint restored to its natural condition. The manipulation was performed in a twentieth part of the time taken to describe it."

If the method of dorsal flexion, when carefully and thoroughly applied, does not succeed, the indication is that the dislocation is a *complex* one, as Jalaguier terms it. This condition is generally, if not always, induced by improper manipulation, namely, by first flexing the phalanx, and then making traction upon it.

This procedure has a tendency to raise the phalangeal border of the glenoid ligament, instead of pushing the whole ligament towards the extremity of the metacarpal bone. The ligament then becomes completely reversed, its palmar surface resting upon the metacarpal bone, and its articular surface looking upward and towards the phalanx. It is interposed between the articular surfaces, and is spread out over the dorsum of the metacarpal bone, extending about a centimeter backwards from its phalangeal attachment (Figs. III and IV), thus forming an insuperable obstacle to the reduction of the dislocation. Ranke,[4] quoted by Jalaguier, opened the joint on the palmar surface in an irreducible dislocation of the index finger, and also of the thumb, and in both cases, found the glenoid ligament interposed between the two articular surfaces. The two sesamoid bones in the glenoid ligament of the thumb, and the single one in that of the index finger, when it exists, offer an additional impediment to the reduction, says Tillaux, as one would suppose. Schüller, says, with reference to the thumb, that it has been made perfectly clear that the difficulty in re-position most frequently depends upon the interposition of the capsule, as he calls the glenoid ligament. Far more seldom, he continues, upon the interposition of the tendon of the long flexor, or upon the incarceration of the head of the metacarpal bone between the muscles inserted upon the phalanx (flexor brevis pollicis). Lawrie, quoted by Kelly, also says that the interposition between the bones of the passive anterior wall of the articular fossa (which is practically the glenoid ligament) is the cardinal difficulty in reduction.

FIG. III.

Numerous are the anatomical reasons which have been given to explain this difficulty of reduction. In the "Encyclopædia of Surgery" (Vol. III, p. 679), it is ascribed to the imprisonment of the phalanx by the lateral ligaments. In Holmes's "System of Surgery," the author, upon the subject, states that the majority of writers have agreed that the flexor brevis pollicis is in some way the chief obstacle to reduction in case of the thumb. Hyrtl says that the head of the metacarpal bone is encircled by the two heads of the short flexors of the thumb as in a tightly-locked vise. Hamilton gives the reasons of many other authors.

In a complex dislocation, then, when the glenoid ligament is reversed and interposed between the two articular surfaces — a condition which is rarely primary, but due to traction made upon the flexed phalanx — what is to be done? The only chance of success, and that a small one, is an attempt to disengage the glenoid ligament, and change the dislocation from a complex to a simple one.

[4] Berliner Klinische Wochenschrift, 1877.

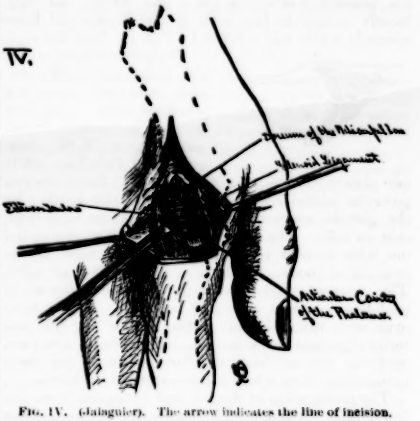

FIG. IV. (Jalaguier). The arrow indicates the line of incision.

To accomplish this, the same method of dorsal flexion is to be used to an extreme degree. The phalanx must be carried, if possible, beyond and behind the torn metacarpal border of the glenoid ligament, and so establish the immediate contact between the articular surface of the phalanx and the dorsal face of the metacarpal bone; then the phalanx can be carried forward, pushing the ligament before it, and finally flexed.

If this does not succeed, then the patient must submit to the inconvenience of a dislocated joint all his life, or recourse must be had to surgical interference. To apply extreme extension by means of such arrangements as the Levis apparatus, Indian puzzle, or the clove-hitch seems to me to be hazardous and irrational. Surgical interference being determined upon — as it should always be when the luxation is irreducible — what should it be, and how executed?

Numerous operations have been devised and done. Resection; section of one or both of the heads of the flexor brevis muscle, in case of the thumb; or of one or both of the lateral ligaments; or section of both muscle and ligaments; and finally, by M.M. Farabeuf and Jalaguier, dorsal subcutaneous section of the glenoid ligament, a method which they declare is both simple and absolutely efficacious. This can be done either subcutaneously or by open wound; the former would naturally be chosen.

The only instrument required for this operation, M. Jalaguier says, is a strong tenotome, with a short blade and a rather blunt point. The landmarks for the index finger are the posterior border of the glenoid cavity of the phalanx, which can be easily felt on the dorsum of the hand, and the extensor tendon. One must also determine the exact situation of the dorsal face of the metacarpal bone in its relation to the phalanx, to see whether or no the two bones are in the same axis as they should be, in order that the middle of the glenoid ligament may lie upon the middle of the dorsal face of the metacarpal bone. In order to favor this, M. Jalaguier suggests that the phalanx be brought back upon the dorsal face of the metacarpal bone. In my experiments with the operation, I found that the exact

position, antero-posteriorly, of the phalanx did not make so much difference, but the two bones must be in the same axis; perhaps the best position of the phalanx is that of an obtuse or nearly right angle with the metacarpal bone. An assistant should hold the finger firmly, and making traction upon it, M. Jalaguier says, which did not seem to me to be necessary. In the thumb, and when a sesamoid bone exists in the index finger, it must be avoided. The tenotome is to be entered about two centimeters behind the base of the phalanx, and immediately outside of the extensor tendon.

Being kept flat upon the dorsum of the hand, the knife is glided under the integument until the articular surface of the phalanx is reached. Then the handle of the knife is raised so as to lower the point, and bearing hard down upon the dorsum of the metacarpal bone, the section of the glenoid ligament is made by withdrawing the knife about a centimeter (Fig. IV). In my trials, I did not always find it necessary to incise the whole extent of the ligament, but sometimes a small incision upon its torn edge seemed to be all sufficient to allow the head of the metacarpal bone to slip back into place. If the reduction does not immediately and easily follow, the knife can be entered again and the operation repeated, for perhaps some portion of the glenoid ligament escaped incision in the former attempt.

It is hardly necessary to say that antiseptic precautions should be used. The finger should be fixed in flexion upon a tampon or wad of some light material placed in the palm of the hand. This, then, is the simple and successful method of operation in irreducible dislocations of the fingers, as proposed and executed by M.M. Farabeuf and Jalaguier, the latter of whom says in recapitulation, that, given a *complex* backward metacarpo-phalangeal dislocation of the thumb, or any one of the four fingers, attempt at first to reduce it by dorsal flexion. In case of failure, do not hesitate to use the bistoury to divide the obstacle. It is irrational to attack the muscles and lateral ligaments whose preservation is precious. The incision of the glenoid ligament made on the palmar surface is difficult and dangerous. The simplest and surest method is to cut this fibrous band on the dorsal face, subcutaneously.

RECENT PROGRESS IN ANATOMY.

BY THOMAS DWIGHT, M.D.

RACE-CHARACTERS IN THE SPINAL COLUMN.[1]

Professor Cunningham has studied the lumbar curve of the spine in different races of men, in a few anthropoid apes, several lower ones, and some quadrupeds. He has used both frozen sections and measurements of separate bones as methods of investigation. He considers that the lumbar curve is a characteristic of less importance than is usually supposed, as he finds it in not only the higher but in the lower apes, and apparently sometimes in quadrupeds. Still it is less marked in the lower than in the higher races of mankind. In the lower races as well as in the higher it is greater in women than in men. The difference between the height of the front and back borders of the vertebræ is stated to be so slight that it cannot cause the curve, but, on the contrary, is a result of it. Though the lower races of men have the curve, the vertebræ are not moulded in accordance with it, as in the higher. It is evident that the deeper the front of the vertebræ, so much more stable must be the curve, and at the same time there must be a loss of power in bending forward. As to the origin of the curve, Professor Cunningham holds that it cannot be due to an immediate and mechanical influence operating upon the vertebral bodies during the life of the individual, for in that case the same character would be found in the lower races and even in anthropoids. It is, according to him, a hereditary condition. In the European, flexibility, which is a necessity with the savage, is sacrificed to stability. We fail to see anything in this theory that accounts for the early stages of the stronger curve of the Caucassian with the longer anterior surfaces of the bodies, but it is fair to say that the original paper, as read before the Academy, has not reached us.

In another paper the same author gives some very interesting results of studies of the spinous processes in the cervical region. "It will generally be noticed that in low races the cervical neural spines are relatively shorter and more stunted than in the European. More especially can this be observed in the case of the neural spine of the third cervical vertebra. This condition is obviously for the purpose of allowing greater freedom of movement in the cervical section of the spine, and is to be associated with other peculiarities present in the lumbar region of the low races, which give to the loin segment a greater flexibility and suppleness." The point, however, which he particularly considers in this paper is whether or not the spines of certain cervical vertebræ are forked at the end. The long spine of the axis is almost invariably bifid, that of the seventh is always simple, and that of the sixth almost always. Those most likely to vary in this respect are those of the third, fourth and fifth, but Professor Cunningham has included the second in his series. The following tables are the most important ones. The first shows the nature of these spines in 15 European skeletons, the second in 24 of lower races.

Second Cervical Vertebræ,	15 bifid,	0 feebly bifid,	0 non-bifid.
Third " "	10 "	3 "	2 "
Fourth " "	9 "	4 "	2 "
Fifth " "	9 "	5 "	1 "

Second Cervical Vertebræ,	18 bifid,	5 feebly bifid,	1 non-bifid.
Third " "	3 "	6 "	15 "
Fourth " "	2 "	7 "	15 "
Fifth " "	3 "	10 "	11 "

These tables speak for themselves, and show the greater tendency to simplicity in the spines of the lower races. The single case of an absolutely simple spine of the axis was in a negro. The author points out that the processes least frequently bifid in the lower races are those of the third and fourth, which are also the smallest, and this arrangement allows greater extension of the neck, as the longer spines above and below can close over these shorter ones.

AN ABDUCTOR LONGUS OF THE LITTLE FINGER.[2]

Dr. Colson has observed this anomalous muscle three times. In the first case the muscle arose from the inferior third of the inner border of the ulna and

[1] The Lumbar Curve of Man and Apes, by Prof. D. G. Cunningham, Nature, February 18, 1886. Abstract of paper read before Royal Irish Academy.
The Neural Spines of the Cervical Vertebræ as a Race-Character, by the same. Journal of Anat. and Phys., Vol. xx, part 4, July, 1886.

[2] Annales et Bulletin de la Société de Médicine de Gand, 1886.

lay against the *flexor carpi ulnaris*. Becoming tendinous, it passed on the outer side of the pisiform, which it grooved, and was inserted into the inner side of the first phalanx of the little finger. It sent also a tendinous expansion to the head of the metacarpal.

In the two other cases the insertion was the same, but in one, instead of arising from the ulna, it arose from the fascia of the *flexor carpi ulnaris*, and, in the other, owing to an accident, its origin could not be determined. Its action appears to be to abduct the little finger. These observations are believed to be unique. The muscle, moreover, is not found in apes, and the author is inclined to think it a case of a progressive anomaly, that is to say, the first appearance of a new muscle.

THE MINUTE ANATOMY OF THE BRACHIAL PLEXUS.[3]

The abstract of this paper, which was read in March, is all we have as yet seen, but we hope the entire paper will soon appear. Mr. Herringham has undertaken to trace the fibres of the spinal nerves through the intricacies of the plexus, and in some cases at least to their ends. He has made 55 dissections of which 32 were of fœtuses. The labor that this implies is great indeed. We do not give his results, which would be of no interest to most readers, but pass on to the laws which he has formulated.

"First. Any given fibre may alter its position relative to the vertebral column, but will maintain its position relative to other fibres.

"Second (*a*) Of two muscles, or of two parts of a muscle, that which is nearer the head end of the body tends to be supplied by the higher, that which is nearer the tail end by the lower nerve.

"(*b*) Of two muscles, that which is nearer the long axis of the body tends to be supplied by the higher, that which is nearer the periphery by the lower nerve.

"(*c*) Of two muscles, that which is nearer the surface tends to be supplied by the higher, that which is further from it by the lower nerve."

The following law applies to sensory nerves:

"Third (*a*) Of two spots on the skin, that which is nearer the præaxial border tends to be supplied by the higher nerve.

"(*b*) Of two spots in the præaxial area, the lower tends to be supplied by the lower nerve, and of two spots in the postaxial area, the lower tends to be supplied by the higher nerve."

The author states that similar results have been reached by others by means of other methods of research.

THE NERVE SUPPLY OF THE FLEXOR BREVIS POLLICIS.[4]

It is well known that the cutaneous distribution of most nerves is very variable and that it is far from uncommon to find more or less of the area usually supplied by a certain nerve occupied by the branches of a neighboring one, but on the other hand, there is very little variation in the nervous supply of muscles. A muscle has indeed been defined as the terminal organ of a nerve and the nerve supply has been made a criterion of the nature of anomalous muscles. Mr. Brooks's paper, in which he shows that variation is common in the nerve supply of the short flexor of the thumb, is a very important one. According to the text books, the outer head is supplied by the median nerve, and the inner by the ulnar. Mr. Brooks gives the result of 31 examinations, of which 5 present the above "normal" arrangement. In 5 more the ulnar supplies both heads; in 2, the median besides supplying the outer head supplies a part of the inner, and in 19 or more than half the cases, the inner head is supplied by the ulnar, and the outer by both ulnar and median.

THE MORPHOLOGY OF THE THYROID GLAND.[5]

This exhaustive paper is based on observations made at Basle where goitre is endemic, and as the author says, it is relatively uncommon to find a normal thyroid at an autopsy. Hence the paper is in a sense a pathological one, but as will appear it belongs also to normal anatomy. The first point considered is the pyramidal process, which is a projection upward from the isthmus or from one of the lateral lobes. Accounts differ as to its frequency. Gruber found it in forty per cent, Luschka in one third, and Zuckerkandl in seventy-four per cent of all cases. Streckeiser found it 104 times in 153 subjects. In 16 of these cases there was also an accessory thyroid. Besides these, there were in 17 cases an accessory thyroid without a pyramidal process. As these accessory glands were in all probability portions separated from the main organ either before or after birth, they may properly enough be held to represent pyramidal processes. If this be admitted, our author finds this process in seventy-nine per cent. As to its origin, it sprang from the isthmus 7 times, from the right lobe 49 times, from the left 47, and once from each lateral lobe. The pyramidal process is usually connected with the hyoid either by the glandular tissue reaching directly to it, or by the interposition of fibrous or muscular tissue. A connection of some kind was wanting only 16 times in these 104 cases. Of the remaining 88 cases, in 55 the connection was by a continuation of the glandular structure, in 26 by ligament and in 7 by muscle. The point of attachment is usually a little to one side of the middle line. An important point in view of the development of the organ is that the connection is usually with the posterior, concave surface of the hyoid bone.

Dr. Streckeiser divides accessory thyroids into true and false; the former being free from the chief gland, while the latter are joined to it by fibrous tissue. Both as a rule have, according to him, a similar origin, being pieces cut off from a pyramidal process. As a larger percentage of true accessory glands is found in persons over forty years old than in the younger, he believes that the separation occurs often long after birth.

The *levator glandulæ threoideæ* is a well-known occasional muscle, but one of which we do not know the relative frequency. Streckeiser has looked for it in 120 subjects and found anomalous muscles 73 times in 46 individuals; which shows that though such a muscle is absent in nearly two-thirds of the cases, when it is found it brings other irregularities with it. Very certainly we do not find it with any such frequency in our dissecting rooms and it is not unlikely that the enlargement of the gland has to do with the development of the muscle.

We pass over the description of the arteries, merely

[3] W. P. Herringham, M.R.C.P. Proceedings of the Royal Society, Vol. xl, 1886.

[5] Virchow's Achiv. Bd., 103, 1886, by Dr. Streckeiser.

mentioning the relations of the inferior thyroid to nerves. It may pass either before or behind the recurrent laryngeal nerve and very often incloses it more or less completely in a loop.[6] With regard to the sympathetic also, there is apparently no certainty on which side of the artery it is to be found. A middle thyroid artery was observed 12 times in 120; precisely ten per cent, the proportion given by Gruber.

As was stated in this series of "Reports" both Zuckerkandl and Kadyi discovered in 1879 glandular tissue near the hyoid bone, sometimes before the fascia of the mylo-hyoid, sometimes deeper between the genio-hyoids, or in the insertion of one of them. Kadyi described particularly a supra-hyoid gland below the *septum linguæ* and occasionally prolonged into it. These glands were of the same structure as the thyroid and occasionally cysts were found in their place. All cysts of this region, however, do not have the same origin and, not to trench on the domain of pathology, we will leave them out of the question. Streckeiser classifies as follows the accessory thyroids of this region which, it is needless to say, are usually very small. First, those before the mylo-hyoid: *præ-hyoid;* second, those between the genio-hyoids or inside one of them: *supra-hyoid;* third, those nearer the tongue above the genio-hyoids: *epi-hyoid;* fourth, those in the hyoid bone: *intra-hyoid.*

The last of these is the most curious. To see it properly, microscopic sections should be made of the decalcified hyoid. It appears to be derived from the *supra-hyoid gland* which may grow into the ossifying or into the ossified bone. It is not found in the fœtus. The intra-hyoid does not show the normal structure of the thyroid but is always in a state of cystic degeneration. One would be inclined to think that this might be accounted for by supposing that a diseased *supra-hyoid* grew into the bone, but this is not supported by observation.

It is known that the thyroid is developed from an outgrowth from the pharynx, though contradictory statements have been made as to the details. According to Kölliker and others, the outgrowth is, or soon becomes, solid in mammals and as it enlarges is connected by a long stem with the epithelium of the pharnyx which at last is cut off. It is known that Bochdalek found in many cases a canal in the tongue running from the *foramen cæcum* and cysts also occur in this region. For these reasons, Streckeiser believes that the *foramen cæcum* represents the starting point of the divertieulum that becomes the thyroid. The gland grows down the neck in front of the hyoid bone, those parts that are found behind it being secondary growths. This theory sheds much light on the origin of certain cysts. The author adds a postscript to his article to state that since he has finished it, the third fasciculus of His's work on the anatomy of human embryos has appeared in which that great authority demonstrates the relation of the central starting point of the thyroid to the *foramen cæcum.* His, however, teaches that the course of the thyroid is behind the hyoid.

— A Pennsylvania man lately attempted suicide with Paris green, and the physician who was called said that he could not have saved him if the poison had not been adulterated. "It's an ill wind," etc.

Clinical Memorandum.

OVERDOSE OF HYDROBROMATE OF HYOSCIN.

BY S. G. WEBBER, M.D.

Immediately after breakfast Miss —— took a teaspoonful of a solution of hydrobromate of hyoscin by mistake for a diuretic. The formula of the preparation was

℞	Hydrobromate Hyoscin	gr. ss.
	Alcohol	ʒ iss.
	Aq.	q. s. ut fl. ʒ x.

thus each ten minims contained a hundred and twentieth of a grain. The teaspoon, being measured, was found to contain one hundred minims, so that the amount taken was about one-twelfth of a grain.

Finding she had taken the wrong medicine, she immediately took a teaspoonful from the right bottle, one containing acetate of pottassa. About an hour later it was noticed that her face was flushed, and on being questioned, she told what she had done. I was sent for. I found her with face much flushed, pulse 120, and very weak; she complained of feeling strange in her head and dizzy, said her hands and feet felt cold, but the hands seemed warm; later she spoke of numbness in hands and feet, and the sound of our voices seemed distant and muffled.

She was given two drachms of wine of ipecac, and within ten minutes mustard and water. Emesis was assisted by draughts of warm water. Whether owing to the food in the stomach or the action of the drug, it was difficult to empty the stomach, and a large quantity of mustard and water was given before all the breakfast was ejected.

About half an hour after the treatment was commenced, her hands and feet felt much more numb, she was very sleepy, it was difficult to keep her awake. The pulse was still rapid and weak. A fifteenth of a grain of morphia was given subcutaneously, and the pulse soon was reduced to 108. In about twenty minutes another fifteenth brought the pulse to 84. The sleepiness continued all day, and there was a distaste for food. The night was quiet, she slept soundly, and the next day simply had a headache.

Reports of Societies.

PROCEEDINGS OF THE BOSTON SOCIETY FOR MEDICAL OBSERVATION.

CHARLES P. STRONG, SECRETARY.

May 3, 1886.

Dr. E. O. Otis presented a paper on

BACKWARD DISLOCATION OF THE PHALANGES UPON THE METACARPUS.[1]

Dr. J. E. Kelly expressed great interest in the paper which he had heard, especially as he had given much attention to the subject some years since in connection with dislocation of the thumb. He corroborated the anatomical description, except with regard to the posterior ligament of the metacarpo-phalangeal articulation, which, in the thumb, had a distinct identity, while, as Dr. Otis had said, it was replaced in the other digits by the extensor-tendons and their expansions.

[1] See page 202 of this number of the Journal.

The specimen which Dr. Otis exhibited corroborated this assertion which Dr. Kelly had made, contradictory to other anatomists in a paper which was published in the *Dublin Journal of Medical Science*, May, 1883, and containing many other original anatomical observations.

In numerous instances of digital luxations, Dr. Kelly had only experienced difficulty in very few cases, and by the strangeness of surgical coincidences, two children fell under his observation shortly after he had written his paper, but in both the dislocation was lateral towards the mesial line of the hand. The resistance was most remarkable, and in these cases, could not be muscular. He considered that the metacarpal head had been forced through a lateral "button-hole" opening in the aponeurosis formed by the ligamentous structures, and the expansions from the numerous tendons surrounding the metacarpo-phalangeal joint, a portion of which intervened between the displaced bones. Acting upon this assumption, Dr. Kelly reduced the dislocations, although with extreme difficulty, by an adaptation of the manœuvre which he has described in his "Notes on Dislocations of the Thumb."

He had also proposed the operation which Dr. Otis had quoted in almost identical phraseology, although an interval of more than two years and a half had intervened between Dr. Kelly's article and that of Dr. Jalaguier, which appeared in January last. Dr. Kelly showed some appliances which he had invented, and which also were figured and described in his paper, and he claimed for them superiority over all other instruments intended to aid in the reduction of dislocation of the phalanges, owing to the absolute control over the dislocated phalanx which they afforded the operator, and to the economy of force consequent on the lesser or more proximate curves which the hand described in the evolutions necessary for the reduction. To his forceps he had added a clip or ratchet, which prevents the phalanx from being crushed by the immense power at the disposal of the surgeon, and he expressed his disapprobation of Levis's apparatus, which was defective as an instrument of fixation of traction and of leverage.

DR. NICHOLS said that prior to the introduction of ether in Paris, he saw Nèlaton attempt to reduce a dislocation for over an hour by all the various methods unsuccessfully, and subsequently accomplish the reduction by cutting the lateral ligaments.

DR. BLODGETT mentioned the frequent occurrence of this accident among base ball players, and the ready and immediate reduction by the methods of forced flexion, as described by Dr. E. O. Otis.

SUFFOLK DISTRICT MEDICAL SOCIETY.
SECTION OF OBSTETRICS AND GYNÆCOLOGY.

ROBERT B. DIXON, M.D., SECRETARY.

APRIL 21, 1886, DR. JAMES R. CHADWICK in the Chair.

Dr. S. W. DRIVER read a paper entitled

OBSTETRIC GLEANINGS; OR EXPEDIENTS AND MISTAKES.

DR. WEEKS, in opening the discussion, said that it was his custom to give fifteen-grain doses of chloral repeated every twenty minutes until forty-five grains had been administered, in those cases where the os was rigid and unyielding. He found by this practice that the labor was shortened and that no unpleasant effects followed the use of the drug.

DR. KINGMAN mentioned the method of delivering the shoulders of the child as it is practised in Prague. The anterior arm is delivered first by carrying the head well back, this bringing the posterior shoulder into the hollow of the sacrum. As the anterior shoulder descends, two fingers of the hand corresponding to the child's back are carried into the axilla, where traction can be made if necessary, and then being advanced along the humerus, the arm is easily swept down past the pubic arch.

The result of this procedure is to greatly diminish the danger of laceration of the perineum by the shoulders and facilitate the delivery.

DR. J. L. SULLIVAN said that in those cases in which Dr. Driver proposed using the muriate of cocaine, namely, where there was great and unusual sensitiveness of the os uteri so that each pain is a dreaded agony, he has used morphine in one-half hourly doses with the effect of not only relieving the excruciating pain, but of causing rapid dilatation of the os. In such cases dilatation is ordinarily tedious unless relief of suffering is by some means afforded.

DR. CHADWICK remarked that he was skeptical about the amount of dilatation of the cervix that could be accomplished with the fingers in an ordinary labor; the hand being without the vagina. If the os is small and the cervix thin something may be gained, but if the external os is rigid and the cervix is not thin then but little will be gained by pushing in two or three fingers. The finger may be hooked over the os and draw it down so as to change its relations to the outlet of the pelvis. If the os is directly under the presenting part it will dilate better and possibly it might dilate if it is pulled forward. If the anterior lip of the cervix is œdematous much may be gained by pushing it up above the pubic ramus. He had found that when an occiput posterior would not stay rotated that if the posture of the woman was changed, for instance, from the right to the left side, then the head would remain where rotated.

DR. WEEKS stated that he had tried dilating the os with the fingers but he had noticed very little benefit therefrom, so that now he has given up interfering with the os and finds that it obviates the frequent use of the forceps. If the cervical lip is swollen something may be gained by pushing it up, and by preventing pressure upon the bladder, paralysis of that organ will be avoided. Dr. Weeks said that he had probably been more fortunate than most practitioners for he had never been obliged to perforate a head, and but twice had he turned a child. In these cases the pains were not good, and the forceps were of no avail. There was no narrowing of the pelvis the fault being with the planes.

DR. REYNOLDS remarked that the expedient of turning was sometimes of great value in occiput posterior positions. He spoke of the plan recommended by Dr. William L. Richardson of putting the forceps on upside down in order to flex the head when rotation would usually take place itself in a few moments. It was not the intention to rotate the head with the forceps. The strong point in Dr. Richardson's method was that rotation would take place when the head was flexed unless there was some great disproportion between the head and the pelvis.

DR. DRIVER, in closing the debate, said that he

thought the small manœuvre of dilating the os assisted labor very much. If the anterior lip should be pushed up he would be afraid that the head would slip through and produce a lateral tear of the cervix. He liked to be sure that the os was thoroughly dilatable.

Dr. Charles Sedgwick Minot then spoke as follows regarding

THE ACTUAL AS COMPARED WITH THE SUPPOSED STRUCTURE OF THE PLACENTA.

The human placenta is composed chiefly of the fœtal chorion, and is not a modification of the allantois, which, as shown by His, extends only to the chorion. In its earliest stage the chorion consists of two layers — the external epithelium or ectoderm and the inner connective tissue. The epithelium shows no really distinct cell boundaries. The connective tissue consists of a glistening matrix in which lie the rounded cells; both these layers are found in the villi, which grow out from the chorion, and abut, by their tips, against the decidual surface of the uterine wall. The umbilical vessels ramify in the connective tissue layer of the chorion, the branches penetrating the villi. These relations are all persistent, hence, the placenta consists of 1, the chorionic membrane; 2, the chorionic villi, with their extreme tips slightly imbedded in 3, the decidua serotina. Contrary to all previous writers, Dr. Minot found the chorionic epithelium to persist normally through the whole period of gestation, and over all parts of the chorionic membrane and villi; it undergoes, however, remarkable metamorphoses, being transformed in spots, which often fuse into larger areas, into a thick layer of cell (Langhan's *Zellenschicht*) which may further be partially or completely degenerated, so forming the layer known as the canalized fibrine layer. The decidua subchorialis is only part of the modified chorionic epithelium. No maternal layer covers the chorion or any part of the villi, except the very tips. The villi do not grow into the glands. The decidua serotina contains very few blood-vessels.

The maternal circulation in the placenta is not yet understood. It is very doubtful whether blood is normally present in the inter-villous spaces during life; if it is present it may enter *per diapedesin*, there being no channels known for a maternal inter-villous circulation. It is possible that the nourishment of the fœtus is really accomplished by a uterine milk similar to that found in ruminants.

Dr. Minot included a summary of the results obtained by the best investigators, and pointed out that the descriptions of the placenta in the standard text-books were, he believed, inaccurate, often extremely so. He related his surprise at having been unable to find in any manual at his command an account of the placenta which would enable one to even identify the prominent parts as seen in sections of the placenta examined under the microscope.

Dr. Minot replied to a question that the same decidual development took place in the uterus and Fallopian tubes, because they have the same tissues. There is a decidua in the Fallopian tube.

Dr. Chadwick remarked that the exfoliation of the decidua at the third or fourth month and the enlargement of the uterus were chief diagnostic signs of extra-uterine pregnancy.

Dr. Reynolds asked if the ends of the villi are embedded in the mucous surface of the uterus to be dragged out in early abortion and leave a broken, depressed surface.

Dr. Minot replied that the villi do go a little ways into the placental decidua, and when torn off may take away some of the latter tissue.

Dr. E. W. Cushing asked whether Ercolani's view, that the covering of the placental villi is maternal and that the decidua is a "new formation," is tenable, and also what is found between the villi.

Dr. Minot replied that Ercolani was in error in regard to both points; that the villi are covered at all times by the fœtal epithelium of the chorion must be regarded as certain; the speaker knew of no reason for considering the decidua as anything more than the altered mucosa of the uterus. Between the villi very often the placentæ examined by Dr. Minot had contained nothing but fluid, or, again, the inter-villous spaces are surcharged with maternal blood; it must be deemed doubtful whether the blood is normally present *intra vitam*. He remarked that even in regard to the gross anatomy of the placenta many of the text-books present certain erroneous statements.

FIBROID TUMOR.

Dr. E. W. Cushing showed a fibroid tumor, with the following history: Mrs. X., fifty years old, had suffered for several years with menorrhagia, which, during the last few months, had been so severe that her physician, Dr. F. E. Corey, of Westboro, had advised her to seek relief in an operation; therefor he had brought her to Dr. H. O. Marcy. On examination, a tumor much larger than a child's head was found, filling the upper pelvic and lower abdominal regions. It presented at the os uteri, like the head of a fœtus (the os being about two inches in diameter); it was, however, submucous and not pedunculated. As it was evidently too large to remove in one piece, the question of laparotomy was discussed, but it was finally decided to remove it per vaginam, and the operation was performed by Drs. Marcy and Cushing at their hospital, aided by Drs. Corey, R. J. P. Goodwin and M. Greely Parker. The vagina was irrigated before and during the whole operation with a hot solution of corr. sublimate 1:2000. There was very little hæmorrhage. On cutting through the mucous membrane, the tumor itself presented, and was seized with the strong Martin double hooks, and brought down as far as possible; then with powerful scissors a wedge-shaped piece was cut out, and the same process repeated until fourteen pieces had been thus removed. In order to accomplish this the spoon-saw was used to shell the tumor out of its capsule, and afterwards Dr. Marcy passed his hand into the opening made with the spoon-saw, and further separated the mass from the uterine wall. By prying the tumor to one side and the other it was possible to reduce it as above, until the fifteenth and last piece was delivered edgewise, being larger than a man's two fists. The cavity was well washed with sublimate solution, powdered with iodoform and packed with iodoform gauze (Grosvenor and Richard's), as was also the vagina.

There was serious shock, relieved by repeated subcutaneous injections of brandy and ergot. On the third day, the temperature, which had remained normal, rose suddenly to 103°, with acute cystitis. This attack was caused by the passage of a catheter, by the nurse, without previous cleansing of the urethral orifice with sublimate solution. The catheter was clean,

but microbes from the vaginal orifice were carried into the bladder, setting up a cystitis, just as it frequently happens after childbirth. Repeated injections into the bladder of sublimate solution 1:5000 soon stamped out the cystitis. During the latter the urine showed great numbers of long, thin rods, some of which were one two-hundredth of an inch in length, with pus cells in abundance. In nutrient gelatine this organism grew rapidly on the surface, not in the needle-track, not fluidifying the gelatine.

Except for this accident the patient did very well, temperature nearly normal, the wound or cavity diminishing rapidly and granulative. The treatment was by careful sublimate irrigations, and iodoform gauze packing, as above.

On the eleventh day, when everything was progressing favorably, the husband of the lady foolishly, and against strict injunctions, persuaded her to get up and put on her clothes, and walk to a chair, he being alone with her while the nurse was at church. That night her temperature went up to 103°, and the next day to 105°. Careful exploration showed that there was a sort of pocket formed by the doubling forward of the uterine wall; this may have been there and contained secretion for some time, but did no hurt until, probably from her getting up, the cavity became septic.

For a few days it was a hard struggle to keep down the trouble, the temperature jumping up from 101° to 105° repeatedly, but plenty of sublimate solution and iodoform, at short intervals, stamped out this trouble also, and the patient was discharged on the fifth week, well enough to return home safely. The tumor was carefully matched and sewed together, forming a round regular mass 4½ x 5 inches, weighing four pounds after some blood had drained from it. The separate pieces as it was removed, averaged about 2 x 3 x 1 inches. The perineum, vagina and cervix were not wounded.

A PIECE OF SILK LIGATURE HALF AN INCH LONG DISCHARGED FROM AN ABDOMINAL SINUS TWO YEARS AFTER AN OVARIOTOMY.

DR. FARLOW showed a piece of silk ligature half an inch long, with the knot still visible, which had remained in the abdomen for two years after an ovariotomy, and which had probably been one of the causes of the long continuance of an abdominal sinus, which closed immediately after the discharge of the ligature. Carbolized silk ligature were used at the operation. The patient made a good recovery, with the exception of a sinus opening near the umbilicus, and into which a probe passed deeply toward the pelvis.

Various attempts were made to cause this to close, but without avail, until one morning, two years after the ovariotomy, the patient, when bathing the sinus, noticed a small piece of what she took to be a bit of tissue. After washing this, she saw that it was a piece of silk, and sent it to me to see if it could possibly have come from the operation. The sinus immediately began to close, and has not opened again although it is nearly seven months since the silk came away. Under the microscope the silk fibres are seen to be in perfect condition. Bearing in mind in what a disintegrated condition we usually find ligatures, even a week after an operation, and the fact that silk ligature is presumed to be absorbed very quickly and completely, we must wonder what conditions enabled this to remain in the body for two years, and apparently in a suppurating cavity.

ANNUAL MEETING OF THE AMERICAN NEUROLOGICAL ASSOCIATION.[1]

JULY 21, 22, 23, LONG BRANCH, N. J.

JULY 23, MORNING SESSION. — THIRD DAY.

EXHIBITION OF THE MEDISECTED ALINJECTED HEAD OF A MURDERER.

DR. WILDER exhibited a very beautiful specimen of the above mentioned head, and remarked that the features of the brain which was thus hardened and exposed in situ are to be discussed at a future meeting in comparison with another murderer's brain; the specimen shown is an illustration of the value of the method and continuous arterial alinjection which has been applied to a head, to brains and to larger bodies, (a child, a chimpanzee, etc.), in the anatomical laboratory of the Cornell University. The doctor remarked the main features of the method were:

(*a*) Reception of the head within twenty-four hours after death.

(*b*) Preliminary marking out of the vessels with chloral to which perhaps weak alcohol might be preferable.

(*c*) Continuous alinjection for a week.

(*d*) Continuity secured by a pressure of 80 mm. of mercury which was afterwards reduced to 40 mm. when the flow became somewhat free.

(*e*) Gradual increase of the alcohol from 65 to 90 per cent.

(*f*) Maintenance of a low temperature 8° to 11°C.

(*g*) Accurate division of the head with a fine saw acting in a mitre box.

(*h*) The small cost. The injected alcohol represented 41.5 liters and 95 per cent., but about two-thirds was regained; so at three dollars per gallon it would not cost eleven dollars, and at seventy-five cents (free of box) only three dollars.

DR. MILLS stated that he did not care to use alcohol for the preservation of specimens, but used in this way it might be different in its results.

DR. AMIDON remarked that a little corrosive sublimate put in the alcohol might secure still better effects.

DR. MILLS asked if there would not be great difficulty with a brain preserved in this manner in separating the pia-mater from the surface of the brain; whether the brain would not be considerably torn. The old method was to put the brains in a solution of chloride of zinc, the membranes could then be readily stripped off in a few days.

DR. WILDER replied that the question of Guiteau's brain could have been more fully discussed if it had been hardened in the skull, and he felt this very desirable in order to preserve its shape. He hoped to combine with this process the preservation of the brain so that the gyra and fissures could be studied. He had been preparing brains for the Museum of the Cornell University for some years and found alcohol to answer all requirements for the purpose of microscopical examinations. He insisted also that the brain should be in the dura, in its own bag, so to speak, then hanging the brain over a pail by the dura, alinjection is commenced; the brain then immediately fills the dura as though it were in the skull and no pressure upon any one point exists.

[1] Concluded from p. 190.

Dr. James H. Lloyd, Philadelphia, read a paper on

MORAL INSANITY: A PLEA FOR A MORE EXACT CEREBRAL PATHOLOGY.

The paper was devoted to a criticism of those who — in the manner referred to by Locke in his "Essay concerning Human Understanding" — confuse in their psychology the *power* with the *agent*. They personify the "faculties" and regard them as distinct agents, each with its own province and powers. This method was inherited from the philosophers, and is shown to have produced the artificial distinctions between "mind" and "brain" — and to have worked confusion, especially in the Scotch School, in the use of such terms as "consciousness" and "idea." The alienists in their writings have not escaped these errors — and many of the artificial distinctions, classifications and symptomatologies which abound in the books are directly traceable to them. Brief allusion was made to the definitions and tests which have been promulgated in the courts, and are found in the writings of Coke, Hale, Blackstone, Shelford, and Chitty.

To these we are indebted for such distinctions as "civic and criminal" and "partial and total" insanity. Also to such tests as "delusion" and "knowledge of right and wrong." These were all shown to be more or less artificial and incomplete from the very standpoint of Locke's Criticism — that is they ignore the individuality of the brain as one acting "substance," and grant to the faculties, or several activities, of the cerebral organ each its own autonomy, and its own disorders and diseases. They erect one symptom into a whole disease, and insist upon the presence or absence of this as a test.

The writer proceeded to an examination of the claims of so-called *moral* insanity as presented by some of the most advanced medical psychologists. This claim proceeds upon an abstraction just such as the reader was cautioned to avoid. It presupposes a distinct moral faculty — which may remain undeveloped in a mind intellectually normal, or may become diseased without affecting the other faculties. This was almost the worst form of abstraction and personification that had appeared in psychology. It is impossible to conceive of a moral or emotional act of mind which does not include the so-called intellectual faculties. In fact, in these acts it is the cerebrum taking on only different (and rapidly changing) modes of action. To say that it is diseased in one of these modes and not in the other is a sophism. It is more nearly correct to say that in an insane man it is the whole mental (cerebral) act — memory, judgment, emotion and will — which is wrong, as that these are all but modes of action of one diseased substance — the cerebrum. More careful analysis would prove this in the cases which are cited in the books as "moral imbeciles" — and which include evidently such diverse types as hysteria, katatonia, paranœa, imbecility, melancholia, and even delusional insanity. The subject has importance because it is often relied upon to acquit a certain class of lunatics in the courts, and almost invariably proves to be a broken reed to him who leans upon it. The paper closed with a reference to the labors of the experimental physiologists — especially Ferari — who have demonstrated the localization of many sensory and motor areas. It is not possible for them to demonstrate the localization of "judgments" and "emotions." These are phases of all cerebration, and, as Ferari distinctly states, exist both in the sensory and motor regions.

Mr. Jastrow remarked that he thought the public at large began to understand this subject better and were more and more in sympathy with the physicians.

The President stated he had great respect for the metaphysical and practical knowledge of Dr. Lloyd, but he must differ with him on some points: though perhaps it might be differences upon terms or expression rather than facts. He did not see what was to be gained by carrying out the ideas as expressed by Dr. Lloyd in regard to nomenclature and classification. In using such terms as monomania, paranœa, and coming to kleptomania or typhomania and even some of those small forms of so-called phobias: we do it understanding what we are doing, but do it as a matter of science and study. Again, Dr. Lloyd remarked that he did not bring forth the cases to prove the propriety of the use of such terms. The speaker thought Dr. Lloyd might not be thoroughly acquainted with all the cases produced in literature which led us to say that there are cases which deserve this designation of moral insanity. Men who have advocated the term moral insanity are perfectly well aware that in every case, unless it is where you have general paralysis, physical and mental, you must have exhibited mental impairment.

The cases to which this term, "moral insanity," should be applied, are cases which have all through life exhibited a preponderance of moral defect, a decided evidence of moral impairment, though in many cases you may find but little intellectual impairment. He agreed with Dr. Lloyd that the term had been used and had been made to cover cases of hysterical insanity, katatonia, etc. The President thought that while paying tribute to Dr. Lloyd's scientific and literary abilities, an acceptance of his ideas would rather retard than aid the advance of science in this direction.

Dr. Gray remarked that there were three classes of insanity; mania, melancholia and dementia: all other forms being simply forms of degrees of these. He did not see how we were to do away with the term, as it was an extremely difficult matter to draw the line sharply: but still we should know what it means and understand it.

Dr. Parsons thought the laity objected to it because it embraced so many forms of disease, it may mean emotional or wicked insanity. But in speaking of a man as having a diseased liver we do not mean to say that he is not sick. His views he thought had been well expressed by Drs. Gray and Mills.

Dr. Mills said he would like to ask a few questions. First whether in discussing the question of insanity, we have any right to use such terms as moral and immoral insanity. If so, in what sense should they be employed.

Do not those who see cases of insanity, frequently see those who present overwhelming predominance of moral or immoral phenomena? In a case, the trial of which lasted four weeks, the man being what we would term a delusional monomaniac plead his own case before the courts and the jury declared him sane. There was little or no immoral defect in this man's case, you could not use those terms.

Dr. Gray asked why we could not have localization in regard to the actions of the mind. If we can have mental symptoms by means of impairment of

localized areas why can we not have localized insanity by impairment of certain areas?

DR. LLOYD in closing the discussion remarked that he had in his paper already answered the subject of moral insanity, that it was something more than mere difference in terms; you quote a case of sudden murder and it is impossible for the man to know why he should do so unless there is something the matter with the brain. As to our courts we should not despise them; they have a right that a physician should express himself intelligently. In the case of a man killing his wife after years of happiness and affection on either side, he may say he killed her because he loved her, his brain is affected, his mind, his intellect is affected. It is, as was said in the paper, a mere word differentiation; it is not a differentiation of things. As to the subject of paranœa, it is a congenital defect of the mind; it comes from the mother's womb; it is hereditary. I do not say there is nothing in a classification.

DR. JACOBY presented for Dr. Rudisch a new portable battery, the chief point being that the cells containing the fluid can be left at home and the zincs and carbons replaced in the box. A current can be obtained from them after being once charged as late as at the end of four weeks. Between the carbons and the zincs a piece of stout asbestos paper is fastened by means of a few thin rubber bands. The fluid used in the battery is composed as follows: sal ammonia one and a half pounds, add six pints of water. The asbestos paper retains in its pores a large amount of moisture acting as a large voltaic pile.

A paper from DR. DERCUM was read, by title

FACTS AND DEDUCTIONS ON THE ACTION OF THE NERVOUS SYSTEM.

This closed the session of 1886.

Recent Literature.

Diseases of the Stomach and Intestines. A Manual of Clinical Therapeutics for the Student and Practitioner. By Prof. Dujardin-Beaumetz. Translated from the Fourth French Edition by E. P. Hurd, M.D., with illustrations and one chromo-lithograph. New York: William Wood & Co. pp. 389. 1886.

Disorders of Digestion: Their Consequences and Treatment. By T. Lauder-Brunton, M.D., F.R.S. London: Macmillan & Co. pp. 389. 1886.

Lectures on Dietetics and Dyspepsia, Delivered at the Owens College School of Medicine. By Sir William Roberts, M.D. London: Smith, Elder & Co. 1886.

These three books have appeared about the same time, and treat of similar subjects. They were all three the reproduction of lectures, and the first two, by a whimsical accident, contain precisely the same number of pages, though in other respects differing materially. They are all three suggestive and instructive books which deserve the space they may take in any physician's library, or the number of cerebral cells which may be required to store up their teaching in the brain. They not only show, however, what great progress has been made in the last ten years by physiology, physiological chemistry, and clinical therapeutics in the elucidation of dietetics and the disorders of the digestion, but also indicate how much remains that is still obscure or but faintly illuminated. The general term, dyspepsia, like the great African continent, is being pierced from various quarters by enthusiastic investigators, who are slowly forcing it to yield up its secrets, and are replacing the vague and the imaginary in the territory which it covers by the precise and the real. The buccal, the gastric and the intestinal dyspepsias are now recognized as perfectly distinct divisions, with distinct causes and subdivisions.

The lectures of Professor Dujardin-Beaumetz, of which there are twenty-five, form a complete and continuous treatise on the diseases of the stomach and intestines from the standpoint of clinical therapeutics. Dr. Dujardin-Beaumetz has published in French a series consisting of three volumes under the title of *Leçons de Clinique Thérapeutique.* The book before us, translated by Dr. Hurd, is really the second part of the first volume of that series; the first part, relating to diseases of the heart and aorta being omitted. This volume originally appeared in 1879, but the translation is from the fourth and revised edition of 1885, and the book profits by the latest discoveries, such as those of Selmi, Gautier, Bouchard and Brieger as to the production by the living cell of toxic alkaloids, ptomaines, leucomaines, etc. Especial attention is given to hygienic therapeutics, to food, and to alimentation.

The translation is well done, and the translator has arranged the notes — which are copious and contain a vast amount of information — at the end of each chapter or lecture, references being made to them by consecutive numbers in the text. There is a good index, and the title-page is preceded by a schematic table of the composition of the principal aliments in chromo-lithograph. This volume forms the May number of Wood's library of standard medical authors.

The basis of Dr. Lauder-Brunton's book is three lectures delivered as the Lettsomian Lectures before the Medical Society of London last year, January and February, 1885. When requested to publish them, the writer found they contained so many references to papers published by him at different periods, from 1873 to 1885, that he decided to include these between the same covers. The book, as presented to the public, consists, therefore, of the three Lettsomian lectures on disorders of the digestion, their consequences and treatment, occupying some eighty-two pages, and fifteen papers on a variety of subjects, more or less nearly correlated, occupying, with the index, the remaining three hundred and seven pages — a paper on "How to Make a Poultice" being among those less nearly related to disorders of digestion. A paper on "Poisons formed from Food, and their Relations to Biliousness and Diarrhœa," though written subsequently to the Lettsomian Lectures, is an important supplement to them. Lauder-Brunton, in common with Beaumetz, anticipates the probable results of a further study of the alkaloidal products of albuminous decomposition, and even suggests in his second lecture on indigestion, biliousness, and their consequences, the possible formation in the intestine of alkaloids having an action like that of some of the known cardiac poisons as an explanation of some cases of sudden death — as in gouty patients; that alkaloidal poisons exerting a slower action are formed is no longer

questioned. Poisoning may yet become a finer art than in the days of the Borgias.

These lectures and papers make a volume which is not only instructive, but eminently readable.

Sir William Roberts's lectures delivered at Owens College School of Medicine, Manchester, do not aim at covering so broad a field as the two preceding books, and are published in an unpretentious little volume. They treat mainly of the dietetics of difficult digestion, and the physiological action of the more common articles of consumption. They contain many useful facts and tables, and many suggestions which should prove fertile. Tea, coffee and alcohol are all shown to be retarders of digestion, and an explanation is offered of their universal and constant use in the too easy and rapid digestion and appropriation of food procured and prepared in highly civilized countries.

On some Forms of Paralysis from Peripheral Neuritis; of Gouty, Diphtheritic, or other Origin. By Thomas Buzzard, M.D., of London. Small octavo. 147 pp. London: J. & A. Churchill. 1886.

This little volume, which is a delight to handle and to read, contains the Harveian Lectures for 1885, with "a considerable amount of material which was unavoidably omitted in the lectures" as delivered, and as published in the *Lancet*. The possibility of the publication of such a book is a mark of the progress that has been made in nervous diseases, and especially of the diseases of the peripheral nerves, for until within two or three years, neuritis was a subject which occupied only two or three pages in our largest text-books, while to-day it is one of the most important of the diseases of the nervous system. After a few brief, but clear pages on the functions of the peripheral nerves, Wallerian degeneration, and the electrical reactions, the author begins with the description of cases of neuritis involving one or more nerves in gouty subjects, which he explains by the local irritation of urate of soda in the nerve-trunks. There can be no reasonable question of this form of neuritis in the gouty, although, naturally, it is a form that the American neurologist rarely meets. In this, as in all forms, the author states that any one of the typical symptoms — pain, numbness, muscular atrophy, or reaction of degeneration — may be absent.

Coming to the multiple forms of neuritis, he states that "there is now ample evidence that a more or less widely spread paralysis may depend upon a degeneration of the nerve-fibres themselves, most pronounced towards the periphery, and independent of any recognizable change in the nerve-centres or roots," which seems to us to be as absolutely proven as that paralysis may result from a lesion of the cord or of the internal capsule. "Such cases may occur in connection with chronic alcoholism, diphtheria, enteric fever, syphilis, tuberculosis, and apparently the widespread disease of Japan, called Kakké or Beriberi, is an endemic form of the same affection. There is some reason, too, to think that exposure to cold, which is a frequent antecedent, may be a factor in the production of the disease."

The author, however, omits to describe that form of multiple neuritis which is not connected with any of the diseases mentioned, and which, as a rule, is of a more acute character, closely resembling an acute infectious disease. Dr. Buzzard seeks to explain the fact of the limitation of the morbid changes to the peripheral portions of the nerves by a toxic influence upon the vaso-motor centres in the cord, diminishing the blood-supply to the nerves. He then gives a clear and correct account of the symptoms of multiple neuritis and of Beriberi, and of the alcoholic form, which, of late, has attracted so much attention. In this form, the prognosis, he thinks, is extremely grave, the muscular atrophy is more pronounced, and there is often much mental disturbance. In alcoholic paralysis, too, there is one symptom which he considers as characteristic of alcohol as wrist-drop is of lead, namely, foot-drop, and when it is present, the question of abuse of alcohol must always be investigated. As regards syphilitic neuritis, his experience as to its frequency has been somewhat different from our own, for he lays but little stress upon it. He justly considers diphtheritic paralysis to be of peripheral origin, and quotes a number of interesting cases. In the section on diagnosis, especial stress is laid upon the differentiation of the alcoholic form from locomotor ataxia, and upon the danger of confusing neuritis and anterior poliomyelitis. The prognosis, after the acute stage, with its dangers to the cardiac and respiratory apparatus, is usually good, except in the alcoholic form. Here, after apparent recovery, further excess may bring on a fatal relapse. The treatment recommended is either symptomatic, or directed against the primary disease. Later on, he advises massage and galvanism. P. C. K.

Materia Medica and Therapeutics. By Charles D. F. Phillips, M.D. Philadelphia: P. Blakiston, Son & Co. 1886.

This volume, of more than one thousand pages, is devoted chiefly to remedies found in the vegetable kingdom; about two hundred pages are given to a consideration of organic compounds and drugs derived from the animal kingdom.

The work is a revised and almost entirely rewritten edition of "The Vegetable Kingdom," by the same author, and completes the treatise on materia medica, the earlier portion of which, on inorganic substances, was published in 1882.

The classification of the drugs derived from the vegetable kingdom is a botanical one and many things are well and briefly outlined which are not found in some of the other treatises on therapeutics. Much care has been taken to arrange the subdivisions of each subject in a way to promote clearness in exposition and to facilitate ready reference to such portion of any subject as the reader may wish to consult.

The most recent remedies are mentioned and receive such consideration as their worth justifies.

In this work there is much to recommend, but it is not pre-eminently superior to the books which we already possess and does not give a more careful and judicial summary of what is known in therapeutics than may be found in other treatises on this subject.

A Manual of Dietetics. By J. Milner Fothergill, M.D., Edin. New York: Wm. Wood & Co.

In the short preface to this book the author says: "The time, indeed, is at hand when systematic lectures on Food will be a part of medical education; while the value of feeding in disease is admitted to be as important as the administration of medicines." On this text we have a book of some two hundred and

fifty pages in which the physician will find much of profit, although something of repetition.

The first part treats of the processes of digestion, and the different forms of food with their preparation, and many a practitioner will here find some useful hints not only for his patient's diet but for his own table.

The second part includes a detailed account of the best dietary for various acute and chronic diseases, from indigestion to diabetes; the need is also shown for a diet which must be varied to correspond to the different stages of development of man from infancy to old age. The book is a valuable contribution to an important subject, and it is a pity that there is no index to make its contents more easy of reference.

The Management of Labor and the Lying-In Period. A Guide for the Young Practitioner. By HENRY G. LANDIS, A.M., M.D. 12mo. pp. 334. Philadelphia: Lea Brothers & Co. 1885.

This book was intended by the author as "a guide to practice, divested of all superfluous or irrelevant details"; in short, a treatise for the physician who thinks he has not time to consult larger and more comprehensive works. It seems to us that if the young practitioner has been well instructed, he will have no use for the class of books to which this belongs, as they contain nothing not found in the larger treatises he is presumed to have used as a student: if, on the contrary, he feels the need of systematic teaching, he would do well to seek it in one of the schools of post-graduate instruction or in the standard works of great masters. It should be said of this book, however, that it is one of the best of its kind: the teaching is sound in the main and in accord with modern practice. The book is clearly written and well printed, and we doubt not will prove serviceable to many busy general practitioners.

— The practised giver of testimonials can always find something gratifying to say of any article submitted for his approval. For instance, the hero of the Lady Franklin Bay expedition, who experienced slow starvation for several months, writes to the proprietor of a canned food: "I regretted that a larger quantity had not been taken by me."

— During the late war, at a period when the success of the Union cause was pretty well assured, President Lincoln was invited by some distinguished engineers of the army to inspect a plan which had been drawn for a very elaborate and expensive system of defence for the city of Washington. After examining the drawings attentively he inquired what was the necessity for the works. "The defence of the capital," was the reply, "in the contingency of a Confederate invasion." The president thereupon was reminded of a story of a debating society of a Western town, where the question was discussed "Why does a man have breasts?" Several nights of debate failed to elucidate the problem until the matter was submitted to a referee who decided "that if under any circumstances, however fortuitous, or by any chance or freak, no matter of what nature or by what cause, a man should have a baby, there might be breasts to nurse it."

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 2, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

THE STATE BOARD OF HEALTH TO INVESTIGATE RAGS AS CONTAGION CARRIERS.

THE subject of the danger to public health through the medium of rags, foreign and domestic, employed in the manufacture of paper, is one which, as our readers are aware, has received a large share of the attention of sanitarians (and we may perhaps add, of speculators in patents for disinfecting appliances) during the past few years. The somewhat protracted series of hearings on the subject before the joint committee on Public Health of the Boston City Government has been concluded, and the committee has reported at considerable length to the Board of Aldermen.

The committee reach the conclusions that the existing regulations of the Board of Health should be modified so as to allow the admission of foreign rags into this port without special treatment when collected in countries where contagious diseases have not prevailed during the six months prior to their shipment, if accompanied by proper evidence of origin; that all other rags should be admitted without special treatment or be disinfected in such manner as the Board of Health shall determine in each instance; that all disinfection should be done under the direct supervision of the Board of Health by their duly authorized agents employed and paid by the city, and only the actual expenses of disinfection be charged the owners or consignees of the rags; that where a difference of opinion in the Board of Health exists as to the necessity or process of disinfection, the State Board of Health should be consulted, and the joint action of the two Boards shall finally determine the matter.

We shall return to this subject again in considering the full text of the committee's report.

The importance of the paper manufacture among the industries of Massachusetts makes it extremely desirable that the facts be ascertained regarding the actual occurrence of contagious diseases fairly ascribable to rags as their source of conveyance. Some work of this sort was done in England by Dr. Bristowe in 1866; and in 1882 by Dr. Parsons, which was published in the supplements to the reports of the Local

Government Board for these respective years. It is with pleasure that we note that the newly organized State Board of Health of Massachusetts, a body especially qualified by its personnel and by the conditions of its appointment for undertaking such a work, has commenced an investigation of this subject.

Circulars have been issued within a few days, to the manufacturing companies using rags, asking for data regarding the kind and amount of rags used, and the number of persons employed in the handling of the rags prior to the time when the latter undergo boiling or chemical treatment, which of course is the limit of viability of any possible contagion that may cling to them. Questions are also asked regarding the precautions as to vaccination, the ventilation of dusting rooms and other means for protecting the health of employees, as well as regarding the occurrence of actual cases of infectious disease among the operatives.

The latter class of questions are, of course, likely to receive the most satisfactory replies through the medical profession. Hence a circular has been prepared for physicians practising in the paper towns, asking for particulars of cases of small-pox among such operatives, with any details that have been learned regarding the source of the contagion, whether from other cases in the neighborhood or with no other evident cause than the rags. Also, in regard to other infectious diseases, especially cholera, whether when epidemic they have appeared sooner or more generally among rag-workers than in the community at large. Moreover, the occurrence of locally infectious or non-infectious diseases, particularly of the skin or of the lungs, due to mechanical irritations are made the subject of inquiry.

It is obvious that investigations such as are here contemplated involve considerable difficulty. For instance, given a case of small-pox in a rag-worker, it is often hard, even if we can exclude any outside source of infection, to assign the responsibility, as between foreign and domestic rags. Most mills now mix the two varieties and it rarely happens that an employee has handled exclusively any grade or packing of rags for a period long enough to cover the period of incubation of small-pox. The only satisfactory solution of any such questions can be made at the time of the occurrence of a case of epidemic disease. In a circular issued by the State Board some months since for the reporting of cases of small-pox, one question has reference to the tracing of the disease to infection by rags. When a sufficient time has elapsed we may hope to gather some useful information by this source though in the present fortunate rarity of the disease it will be long before many cases of this sort can be collected. Meantime it is to be desired that physicians whose field of practice covers the paper-mill towns will make special effort to elucidate the etiology of all the cases of infectious disease which occur in rag-workers. Any physicians who have not received this circular can, we learn, obtain a copy by addressing the State Health Office. The manufacturing corporations also can do a good service at once to sanitary science and to their own interests, by favoring such investigations; inasmuch as the accurate determination of the limits of danger from this commodity is the best guarantee for the removal of all unnecessary quarantine interference with the important commercial interests involved.

THE HYGIENE OF HOT WEATHER.

THE excessive heat of a considerable portion of the summer is likely to injure man in two ways, first by its direct effect on himself, and second, by rendering his environment unsuitable for the promotion of the most complete health.

The most direct effect of heat on the human system is a lowering of muscular tone; this manifests itself by general muscular relaxation and vascular dilatation. Under the influence of heat the sphygmograph shows a feeble blood pressure; the capillaries are unduly filled; this is especially true of the cutaneous circulation. If the functions of the skin seem thereby, to be rendered more active (witness the increased perspiration of hot weather, and the wonderful mechanism for bodily cooling connected therewith), it is also certain that those functions are more easily deranged from heat than from cold, and it is in tropical climates that we see such cutaneous affections predominate as lichen tropicus, erythema caloricum and solare, lepra and eliphantiasis.

The relaxed condition of the bloodvessels of the alimentary canal and liver favors hyperæmias and fluxes. There is a physiological congestion peculiar to the liver in hot weather and in hot climates; this organ removes from the blood combustible material in the form of taurine and glycocol, and stores away in its cells glycogen, thus opposing over-production of heat in the economy. To this hyperæmia natural to the hot season, there is added a congested condition of the portal and mesenteric veins, hence the liability to catarrhal fluxes. Excesses in eating and drinking are sure to increase the engorgement, whence often result hepatitis, bilious diarrhœa and intestinal catarrh.

As for the action of external heat on the nervous system, if the impressionability of the reflex and seasonal centres is heightened, it is owing to the vascular hyperæmia resulting from the diminished tone, and neither the nutrition of the nerve centres, nor their capacity for the performance of function is up to the level of completest efficiency. Hence the languor which is experienced in hot weather, the difficulty in the execution of mental tasks, and the often disturbed sleep; in fact it is a matter of common observation that the sleep of summer is less in amount and less profound than that of winter. Excessive heat has been known to cause meningitis, and exposure to extreme heat certainly predisposes to cerebral affections. It is worthy of note in this connection that in some experiments of Claude Bernard the long-continued application to the heads of animals of heat a

few degrees above the temperature of the body was sufficient to induce attacks of acute meningitis.

As far as the respiratory function is concerned, it has been proved that a high temperature determines a more feeble consumption of oxygen and a diminished excretion of carbonic acid, hence it is that the conditions for the production of organic and voluntary force are less completely realized in hot than in cold weather.

The second way in which an elevated temperature can injure man is indirectly, by making his environment unwholesome. The summer is the season when decompositions are rife and the atmosphere is pervaded by mephitic vapors, and bacteria of both benign and morbid kinds abound. The air, moreover, rarefied by the heat, contains less oxygen than cold air.

Not to mention pestilential diseases frequenting certain localities (the grave bilious fevers of Madagascar, the yellow fever of the delta of the Mississippi, the cholera of the banks of the Ganges, the malaria of some parts of our own country), it is a common experience that a large part of the duties of sanitary boards consist in the endeavor during the hot months to render the atmosphere of our crowded cities less unwholesome, and this, by suppressing some of the multitudinous foul sources of contamination.

The hygiene of hot weather may be summed up in a few words. There is a diminished demand for, and diminished ability to digest, food, hence the indulgence of the appetite should be moderate. Foods should be chosen which give the maximum of nutrition with the minimum of work on the part of the digestive organs. An excess of fats deranges especially the stomach, an excess of sweets and proteids the liver; alcohol congests the entire portal system. A moderate allowance of fresh meats or fish, bread, succulent fruits and vegetables with milk, cocoa, tea and coffee seems to be the most judicious dietary, and all late suppers and supplementary lunches are to be avoided.

The habit of eating ice-creams and drinking ice-water at all hours is to be deprecated. Over indulgence in ice-water has produced not a few attacks of nausea, indigestion, diarrhœa and syncope, and has even caused death. Bottle-fed infants are especially liable to suffer from indigestion during the hot weather, not only on account of the depressing effect of heat on the vital functions, but from the difficulty of obtaining milk of a pure quality (at least in cities), and of keeping the bottle scrupulously clean; here we often witness the triumph of pancreatized milk, so much praised of late by leading authorities in Pædiatrics.

As the muscular and nervous systems are enfeebled by excessive heat, the propriety of great moderation in labor both of body and mind is obvious. At this time of the year, common sense and sound physiology dictate to denizens of the town the propriety of spending a season at the beach or among the mountains; the benefits of such a sojourn are too universally known to need insisting on.

The importance of frequent cold ablutions is also everywhere recognized. By judicious cold douches, cold baths and especially sea bathing the tone of the voluntary muscles and bloodvessels is promoted, visceral congestions are relieved, the general blood distribution is equalized, and the functions of the skin are favored.

Many a literary, business and professional man keeps himself in trim for hard work (which during the hot season he is unable to shirk) by the invigorating effects of cold bathing, with just enough exercise in the cool of the day to keep the muscles in a fair state of nutrition and tonicity.

Lastly, it is the plain duty of every man to do his utmost, by attention to the cleanliness of his premises, and removal of all sources of foul smells and rank emanations (which, if they are not the bearers of disease germs, may yet poison the air of respiration and disturb digestion), to make his surroundings wholesome to himself and others; to provide for himself a plentiful supply of pure air and water; and keep the apartments in which he spends most of his time thoroughly ærated and if possible cool. Such are some of the rules pertaining to the hygiene of hot weather; they are not, however, applicable to all classes of society, such as the pork-and-bean-fed haymakers on the salt marshes, or even to physicians at the fashionable watering-places.

THE HEAT CENTRE.

AT the recent session of the Helvetian Society of Natural Sciences at Geneva, Professor Girard gave an interesting account of some late experiments of his in Schiff's laboratory to ascertain the location of the heat centre. These experiments which were made on hares, have led him to conclude that the cerebral centre of thermogenesis is the corpus striatum. Every lesion affecting this body in its median part produces a pronounced hyperthermia, which does not result from spasm of the vaso-constrictor nerves of the skin, but from an augmentation of caloric production. Electric excitation of this region, which is followed by a marked augmentation of heat, justifies the assertion that the hyperthermia is a phenomenon of excitation and not of paralysis. Moreover, after puncture and irritation of this region of the cerebrum, there was a considerable increase in the quantity of nitrogen excreted in the urine, indicating an acceleration of the organic combustions; this was accompanied by notable emaciation of the animal. Girard considers the thermogenetic centres as including not only this median portion of the striate body on both sides, but all the subjacent parts to the base of the brain. There is here, according to him, an apparatus whose excitation increases the production of animal heat and which probably concurs under physiological conditions to regulate heat productions. In answer to the question, "Is the artificial hyperthermia thus obtained identical with fever?" he answers, No. Augmented heat production and diminished heat emission — such in his

view, are the two necessary factors of that pathological calefaction which constitutes fever. But the last of these factors was wanting in his experiments.

DR. OLIVER WENDELL HOLMES.

(PHŒBO ANTE ALIAS DILECTUS.)

All the friends and admirers of Dr. Oliver Wendell Holmes — and among them we know all the readers of this Journal may be counted — will rejoice at his safe return to his native land and his own home after an absence of four months, most of which time has been passed in England. The return voyage was happily completed upon the seventy-seventh birthday of our honored colleague and fellow-citizen. The added year seems to be borne with the elasticity to which we have so long been accustomed, and even the new honors heaped upon the Autocrat have failed to bend his erect figure. Oxford, Cambridge and Edinburgh have all three bestowed distinguished honorary degrees upon him, and the many other marks of respect and appreciation of which he has been the recipient were well merited and well and gracefully bestowed. He must indeed be a churlish chauvanist who begrudges either them or the pleasure which they have given. There is no truer American and none more devoted to the best interests and highest standards of his own country than Dr. Holmes, as the past fifty years of his life and work may prove to any one who considers them.

On the anniversary of the battle of Bunker Hill, and the anniversary of the death of Addison, the orator of the day in the Senate House of old Cambridge, when conferring upon this American the degree of Doctor in Letters, after referring to him as one who "Phœbo ante alias dilectus" had received from Apollo both the gift of medical learning and those of eloquence and soul, concluded his felicitous Latin in the following words:

"Videor mihi vatem quendam canentem audivesse, illum cujus in corde æstas æterna floreret, non vocandum esse senem. Equidem juventutis perpetuæ fontem illum quem trans æquor Atlanticum, Hispanorum nautæ frustra quærebant, nautam hunc feliciorem, non fabulosas inter insulas sed Academicæ juventutis in amore perpetuo, in amore mutuo, invenisse crediderim. Trans occidentis amplum illum sinum, levi phaselo vectus, diu naviget; nautili illius ritu, quem versibus tam pulchris descripsit, indies 'per ampliora ad altiora' tendat. Suam Academiam, per tot sæcula feliciter conservatam, intra paucos menses carmine sæculari iterum celebret, diuque superstes ipse exornet; nostræ denique Academiæ honoris causâ adscriptus, diu et nostrum et totius litterarum reipublicæ ad fructum floreat, vigeat, valeat, litterarum doctor, Oliver Wendell Holmes."

In due time, perhaps, Dr. Holmes's travels may bear fruit in print, and we will wait patiently to know whether he found "that Englishman precisely like himself," for has he not said: "I have no doubt each one of us has somewhere our own facsimile, so like in all things, except the accidents of condition, that we should love each other as a pair of twins if our nature could once fairly meet. I know I have my counterpart in some State of this Union. I feel sure that there is an Englishman somewhere like myself — I hope he does not drop his H's."

MEDICAL NOTES.

— The Spanish Ministry of Justice has arranged for the establishment in Madrid, Barcelona, and Seville, of laboratories of forensic medicine. After the middle of September, analyses which may be ordered by magistrates will be conducted in the new institutions — a provision enabling experts nominated in the interests of accused persons to be present during the performance of such analyses.

The *Nation* tells an excellent New Haven story of a Hartford business man so anxious to get back to work after his mid-day dinner, that he asked his guest "whether he would mind eating his pie in the street." It being a "New Haven story," the scene is perhaps necessarily laid in Hartford, but there is, unfortunately, good reason for believing that the *locus* of the story could be with truth extended pretty widely over the country.

— Mr. Thomas Smith, of England, recently performed successfully the supra-pubic operation of lithotomy, and removed a stone weighing twenty-four and a half ounces. This was claimed to be the largest stone that had been extracted during life, but in the *Lancet* of January 16th last, Dr. W. B. Hunter, of Londonderry, reported a case of calculus weighing twenty-five ounces, removed by Joseph Hunter, M. L. S., from a native in the Madras Presidency. The patient lived three days. Mr. Smith's patient recovered.

Mr. Reginald Harrison exhibited at the late meeting of the Surgical Section of the British Medical Association, a uric and calculus removed *supra pubem*, and requiring obstetric forceps for its extraction. The size was not given, though Mr. Harrison stated it to be the "largest on record."

— At the last Manchester Assizes in July, says the *Lancet*, a solicitor and a builder were sentenced, the former to ten and the latter to seven years' imprisonment for arson. In December last they took a shop in Hulme, fitting it up as a cigar shop, but not living upon the premises. The stock was valued at about £2 10*s.* and the fixtures were of the thinnest wood, and under the counters were large quantities of shavings. They insured the stock and fixtures for £950 in April last, and in the night of the 19th of June a fire broke out, and on the arrival of the fire-brigade, there were found to be three distinct fires in different parts of the shop and house. The two firemen who first entered were nearly suffocated by a dense white smoke, and applied to Mr. Heslop, Divisional Surgeon, Man-

chester police force, a day or two after, complaining of a rawness of the throat and chest, very different from anything they had experienced before. On account of what they told, Mr. Heslop burned some phosphorus in their presence, and they at once recognized the smell. Some phosphorus was then placed in some shavings, and it ignited spontaneously in about eight or ten minutes, and in sawdust in about twenty minutes. The gas-pipes had been cut, and the ends joined with India rubber tubing. The defence was that there was no evidence that the prisoners were the men who set fire to the place.

Miscellany.

THE FRENCH ACADEMY'S REPORT *vs.* LIQUORS AND LIQUOR SALOONS.

THE French Academy of Medicine has recently taken action respecting the alcoholization of wines, adopting the report of a committee appointed to inquire into the public danger from the use of the wines of commerce. The government is urged to take the strongest measures to prevent the introduction of artificially alcoholized wines into France. The report also calls for a large reduction in the number of wine shops, and for a rigid enforcement of the laws for the suppression of drunkenness.

THE OFFSPRING OF THE BLIND.

MR. SIMEON SNELL, writing in the *British Medical Journal*, August 7, gives the results of investigations undertaken to ascertain the influence upon the offspring of the marriage of the blind. In every instance, to inquiries as to sight and the formation of the eyes of the children, he was assured that vision was perfect and the ocular condition normal. A similar answer was returned to questions respecting hearing and bodily deformities. The latter were absent, and hearing was always stated to be good.

The results obtained are somewhat at variance with those recorded by other observers. Magnus investigated fourteen instances of married couples in whom one or both were born blind, or became blind at an early age, and found that, out of thirty-four children begotten of these marriages, eight, or 23.5 per cent., were either blind or weak-sighted.

He mentions, moreover, that a man who had lost his sight by blennorrhœa neonatorum had two children affected with microphthalmus. Fuchs states that he was acquainted with a physician who had congenital microphthalmus of right eye, and whose father had lost an eye by irido-cyclitis, when a child. He says, also, that the connection of the eye-disease between father and child is indubitable, for Deutschmann obtained analogous results in his experiments on animals.

The author gives in tabular form the facts regarding the various families, sixteen in number, in which his inquiries were made.

He properly admits that the numbers are too small to be anything else than an instalment to an interesting inquiry. As to the case of retinitis pigmentosa, no evidence was elicited of children suffering from nyctalopia.

Another point will hardly escape notice, and that is the small proportion of births. The experience of managers of blind institutions is that the workers are very disposed to wedlock, and this notwithstanding that, in consequence of the small wages they can necessarily earn, marriage is, at all events in some places, discouraged.

Of those couples who were both blind, after excluding the recently married, there are three, and only one has children (two). One young man has had two blind wives, and neither has borne children to live; triplets by the first wife died immediately after birth. There are ten men with sighted wives, and, excluding one whose wife had ceased to bear children before his blindness came on, there are left nine, with twenty-six children between them, or less than three per family. Adding to this number the three blind couples with two children, there are a total of twelve, with twenty-eight children, or two and one-third per family. It would almost seem, therefore, that, though prone to marry, such marriages are less than usually fruitful. Farr placed the number of children per wife in England at 5.2.

POISONING BY ICE CREAM.

V. C. VAUGHAN, writes in *Science* as follows:

"No chemist certainly would suppose that the same poison exists in all samples of ice cream which have produced untoward symptoms in man. Mineral poisons, copper, lead, arsenic, and mercury, have all been found in ice cream. In some instances these have been used with criminal intent. In other cases their presence has been accidental. Likewise, that vanilla is sometimes the bearer, at least, of the poison, is well known to all chemists. Dr. Bartley's idea that the poisonous properties of the cream which he examined were due to putrid gelatine is certainly a rational theory. The poisonous principle might in this case arise from the decomposition of the gelatine; or with the gelatine there may be introduced into the milk a ferment, by the growth of which a poison is produced.

But in the cream which I examined, none of the above sources of the poisoning existed. There were no mineral poisons present. No gelatine of any kind had been used in making the cream. The vanilla used was shown to be not poisonous. This showing was made, not by a chemical analysis, which might not have been conclusive, but Mr. Novie and I drank of the vanilla extract which was used, and no ill results followed. Still, from this cream we isolated the same poison which I had before found in poisonous cheese (*Zeitschrift für physiologische chemie*, x, heft 2) and demonstrated its poisonous properties by experiments upon cats. Moreover, by adding a piece of the solid portion of the poisonous cream, about the size of a filbert, to some normal milk, and making cream with this milk, following the details of the maker of the Lawton cream, omitting, however, all flavoring, I obtained a highly poisonous cream. Does this not prove that the poison may be produced by fermentation in good milk? A detailed account of my experiments may be found in my report to the Michigan State Board of Health."

Correspondence.

ON GLYCOGENESIS.

Mr. Editor, — In this venerable German town I read your highly instructive article on "Glycogenesis and Glycosuria" with so much more interest as I myself suffer from glycosuria. Will you allow me then to make a few remarks on one or two points in your paper about which I do not quite agree with you. You state, "Into this substance (glycogen) all the saccharine products of digestion must be converted before they are available for the uses of the organism."

Now, Mr. Editor, I feel very much like calling this sweeping assertion into question, as it is opposed to the results obtained by experiments, which have been carried on later than those of Bernard. I allude to Harley's experiments (the urine and its derangements), that led him to an entirely opposite conclusion as far as the *omnivora* and *herbivora* are concerned. Whilst Harley, of course, agrees with Bernard that *animal food* cannot be transformed into sugar (glucose) without *an intermediate stage* (glycogen) between the proteid substances on the one hand and glucose on the other, he finds in the case of *amylaceous foods and saccharine meals that there is no connecting link at all.* According to him, all starchy and saccharine foods, as they pass along the alimentary canal, are transformed into *glucose at once.* Says Harley, "The transformation of amylaceous matters into glucose during their sojourn in the alimentary canal is not the result of accident, but the sequence of an unalterable law, which is equally in force in or out of the body, so long as the physical conditions necessary for its action are in operation. Thus, if an ounce of boiled arrowroot in a test tube be mixed with a little saliva, or have added to it half a dozen drops of pancreatic juice, all the starch contained in the arrowroot will infallibly be changed into sugar in the course of a few minutes, and for this operation the intervention of no other agency than that of a temperature equal to that of the human body is required. A precisely similar change occurs in the animal organism, and the sugar thus formed is absorbed by the mesenteric veins and lacteals, and of *necessity forms part of that met with in the circulation.*"

Dr. Harley arrived at this conclusion, so opposite to the doctrine that all the sugar met in the circulation is manufactured by the liver, by finding a great amount of sugar in the blood of the *portal vein* and *chyle* of the *thoracic duct* of animals fed on saccharine food three hours after they had partaken of it. Whereas it is true, that in the case of *carnivora* there is no sugar to be found in the portal, but a great amount in the hepatic vein; in the case of omnivora sugar is met with in either of them, a fact that demonstrates that not all the saccharine or amylaceous products of digestion must first be converted into *glycogen* before they are of any use in the complex nutritive process of our organism. The *modus operandi*, how cane-sugar is converted into grape sugar (glucose) by means of the digestive juices (pancreatic juice, etc.), is at least not shrouded in greater mystery than that of the metamorphosis of proteids into glycogen and (sugar afterward) by the agency of the liver.

G. Liebmann, M.D.

Augsburg, Germany, August 15, 1886.

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 21, 1886.

Deaths reported 2,310: under five years of age 1,093: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 697, consumption 329, lung diseases 105, diarrhœal diseases 467, diphtheria and croup 82, typhoid fever 46, malarial fever 26, whooping-cough 28, measles 19, scarlet fever 18, cerebro-spinal meningitis 10, typhus fever one. From whooping-cough, Brooklyn nine, New York eight, Pittsburg six, Baltimore three, Lynn and Chelsea one each. From malarial fevers, New Orleans 13, New York eight, Brooklyn and Baltimore two each, Providence one. From scarlet fever, New York six, Pittsburgh four, Cincinnati, three, Boston two, Brooklyn, Providence and Taunton one each. From measles, New York 10, Nashville two, Brooklyn, Boston, Baltimore, Cincinnati, Pittsburgh, Cambridge and Salem one each. From cerebro-spinal meningitis, New York and Nashville two each, Boston, Baltimore, New Orleans, Worcester, Taunton and Gloucester one each. From typhus fever, Cincinnati one.

In the 21 cities and greater towns of Massachusetts, with a population of 957,625 (population of the State 1,941,465), the total death-rate for the week was 23.50 against 24.56 and 25.02 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending August 7th the death-rate was 19.9. Deaths reported 3,472: infants under one year of age 1,373; acute diseases of the respiratory organs (London) 148, diarrhœa 657, measles 62, whooping-cough 55, scarlet fever 43, fever 38, diphtheria 13, small-pox (Liverpool) one.

The death-rates ranged from 10.0 in Halifax to 31.4 in Leicester; Birmingham 16.2; Hull 10.4; Leeds 22.5; Liverpool 21.6; London 20.4; Manchester 24.4; Newcastle-on-Tyne, 16.8; Nottingham 16.8; Sheffield 16.4; Sunderland 19.6.

In Edinburgh 19.3; Glasgow 20.6; Dublin 17.6.

For the week ending August 7th, in the Swiss towns, there were 23 deaths from diarrhœal diseases, consumption 22, lung diseases nine, whooping-cough four, erysipelas, diphtheria and croup each two.

The death-rates were: at Zurich 19.1; Geneva 13.1; Basle 17.0; Berne 16.0.

The meteorological record for week ending August 21, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, Aug. 21, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 21, 1886, TO AUGUST 27, 1886.

WOODHULL, A. A., major and surgeon. Granted leave of absence for fourteen days, to take effect on or about September 1, 1886. S. O. 197, A. G. O., August 25, 1886.

TAYLOR, M. K., major and surgeon. Leave extended one month. S. O. 195, A. G. O., August 23, 1886.

LANDERDALE, J. V., captain and assistant surgeon. Granted leave of absence for two months, with permission to apply for one month's extension, when his services can be spared. S. O. 195, A. G. O., August 23, 1886.

GANDY, CHARLES M., first lieutenant and assistant surgeon. On expiration of his present leave of absence, relieved from duty in the Department of the East and assigned to duty in the Department of Texas. S. O. 195, A. G. O., August 23, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING AUGUST 28, 1886.

CLARK, JOHN H., medical inspector. Ordered to special duty Portsmouth, N. H., and Widow's Island.

KINDLEBERGER, D., medical inspector. Ordered to hospital, Washington, D. C., October 1, 1886.

GIHON, A. L., medical director. Ordered to hospital, Mare Island, Cal., October 15, 1886.

ROBINSON, SOMERSET, medical inspector. Detached from hospital, Mare Island, Cal., October 15, 1886, and wait orders.

SPEAR, J. C., medical inspector. Ordered to naval laboratory, New York, September 28, 1886.

BLOODGOOD, DELEVAN, medical director. Ordered to hospital, Norfolk, Va., September 29th, 1886.

TAYLOR, J. Y., medical director. Ordered to naval laboratory, New York, September 29, 1886.

DEAN, R. C., medical director. Detached from naval hospital, New York, and wait orders.

SIMON, W. J., surgeon. Detached from United States Steamship "Constellation," for special duty at Naval Academy, Annapolis, Md.

HENRY, C. P., assistant surgeon. Ordered to hospital, Philadelphia, Pa.

FITTS, H. B., passed assistant surgeon. Detached from hospital, Philadelphia, Pa., and wait orders.

STONE, E. P., assistant surgeon. Ordered to Receiving ship, "New Hampshire."

SOCIETY NOTICE.

GYNÆCOLOGICAL SOCIETY OF BOSTON. — The next regular meeting of the Society will be held at the Medical Library Rooms, No. 19 Boylston Place, on September 9th, at 4 o'clock, P. M. Papers: Dr. J. E. Kelley, "The Ethics of Abortion as a Measure in Legitimate Practice." Dr. W. Thornton Parker, "The Removal of a large Vaginal Tumor."

H. J. HARRIMAN, *Secretary*.

THE TREATMENT OF LATERAL CURVATURE.[1]

BY EDWARD H. BRADFORD, M.D., OF BOSTON.

The principles of treatment of any disease depend largely upon the theory of causation. This is particularly true of lateral curvature, and it is for this reason impossible in dealing with the subject to avoid referring to the vexed question of etiology. Although many other theories have been advanced, it may be accepted as more than probable that the distortion is the result of superincumbent weight pressing upon a weakened spinal column, held in a position out of the vertical line. This view is supported by clinical facts as seen in a series of cases of varying grades of severity; by the fact that in early cases the deformity disappears when the weight is removed from the spinal column (by recumbency or suspension); by the obser-

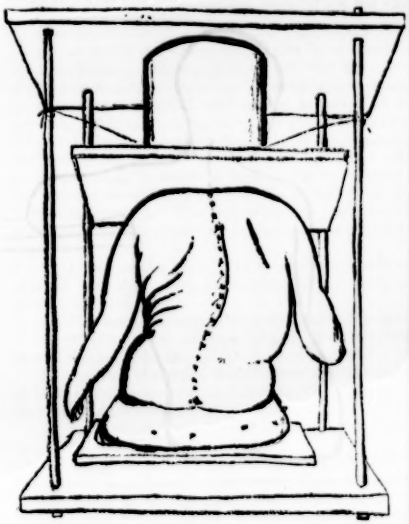

Fig. 1.

vation that in quadrupeds where the spinal column is horizontal lateral curvature does not occur.[2] Pathological specimens would also confirm this view, and the results of experiments demonstrate the fact that lateral curvature can be produced by downward pressure[3] (Fig. 1).

No better illustration can be furnished than the accompanying specimen from the Warren Museum, which shows the effect of weight falling upon a weakened skeleton. The lower extremities and the spinal column have bent under their load, while the long bones of the upper extremity, which have no weight, have remained straight (Fig. 2).

That weight rarely falls in a vertical line on the spinal column an inspection of figures in action makes evident (Figs. 3 & 4), as well as an examination of the exact modelling of the antique statues, notably the Borghese Achilles, the Farnese Hercules, the Dying Gladiator, the Germanicus. In fact the spinal column is rarely, if ever, in a vertical position; and the superincumbent weight would induce a deviation to the right or left, varying in extent in different attitudes. Whether the curve should be a long upper with a short lower curve, or the reverse, or compensating curves of equal size, will depend partly upon the favorite attitude, and partly without doubt upon the power of resistance of certain parts of the spinal column.

The treatment of lateral curvature should vary according to circumstances of the case, and largely according to the stage and degree of the affection. It is manifestly as irritational to incase in a stiff corset,

Fig. 2.

certain to promote muscular atrophy, a trunk dropping to one side from a want of muscular development, as to attempt to correct a fixed curve with osseous change by muscular exercise. Cases should be treated according to the indications. Bearing in mind the factors which cause the distortion, the aim of treatment would be,

1st, To remove the superincumbent weight.

2d, To develop the strength of the structure of the spinal column.

3d, To keep the spine as far as possible from deviating from the vertical line.

The two means for accomplishing the first are recumbency and suspension, and they can only be employed as adjuncts. For it is manifest that it is impossible to make quadrupeds of patients, or to imprison them to a couch during the growing years, or

[1] Read at the annual meeting of the Massachusetts Medical Society June 9, 1886, and recommended for publication by the Society.

[3] Boston Medical and Surgical Journal, March 16, 1886.

until danger of the yielding of the spine has entirely past. Suspension is evidently only of temporary assistance. Little or nothing can be done by drugs in the way of strengthening the tissue of bone. The distortion, however, is essentially one of childhood, beginning in the majority of cases at from seven to ten years of age,[4] and in the process of growth the bone will gradually develop to the normal strength. A great deal, however, can be done towards maintaining a proper position of the spinal column, and it is in this direction that the chief efforts in treatment should be directed.

There are three methods worthy of consideration, namely:

The postural,
The gymnastic, and
The mechanical.

The postural treatment is that method where correction is sought by instruction in proper attitude. As

FIG. 3.

a raw recruit is taught the position and carriage of the soldier, so children are to be drilled into standing and walking erect. This method is suited for the simplest cases. To be thoroughly carried out, it requires that the patient should daily be exercised in walking, standing and sitting properly for a specified time under the direction of some competent person. The back should be bared, and any deviation from the proper position in standing, sitting and walking should be carefully noticed. When resting during the hour of drill the patient should remain incumbent. After the drill is over such precaution should be taken as will prevent the persistence for any length of time of a faulty attitude. This should not be done (out of the drill time) by constant correction, but by the proper arrangement of the play hours, a supervision of the chairs when reading and studying. Walking, running and active games should be encouraged. Reading, except in proper position, should be discouraged. A certain amount of time should be given to proper rest of the back. A fruitful source of faulty attitudes in sitting is furnished by the chairs, which, not fitting the child or supporting the back properly, induce the patient to sit sideways, the trunk being supported on one tuberosity of the ischium and on one elbow. The chair which the child is to sit in for any length of time should be narrow, and not deeper than the length of the thighs or higher than the length of the legs; its back should not be above the shoulders and should be arched so as to fit in the hollow of the back; or if this is not practicable, hard cushions should be replaced on the back of the chair, so fitted as to act as a proper support. An ordinary steamer-chair, furnished with a swinging book-rest, gives an excellent and ready means of reading without great danger of improper attitude. In school it should be seen that the seats are not too far from the desks nor too high; and foot-

FIG. 4.

rests should be fitted for both feet. Counteracting a tendency to sit sideways, the desk or table should be near enough to the chair to prevent lounging. Children at home are usually expected to sit in chairs made for adults, and the chairs do not, as a rule, fit properly. In cases where great care is needed, chairs suitable to age and size of the child should be furnished.

It is not so easy to prescribe rules for the avoidance of faulty position in standing as in sitting, when the chair in a measure regulates the attitude. Standing with the weight chiefly on one leg probably results more as a matter of habit than from a unilateral muscular weakness; when it becomes habitual and instinctive, it is with difficulty corrected. Under these circumstances, the child should not be restricted in walking or active play, which give a constant change in attitude, but should, so far as practicable, be prevented from standing for any length of time.

[4] Eulenberg (Die Seitliche Rückgrat's Verkrümmungen, Berlin, 1876). Keteh, New York Medical Record, April 24, 1886.

The usual bad habits of position are as follows: standing on one leg, at too low a table, sitting in a twisted position, sleeping always on one side, with too high a pillow for the head.

In most early cases the faulty attitudes are clearly the result of muscular weakness. The growth in size has not been accompanied by a corresponding development of muscle. This condition is frequently met in rapidly growing children, and is one of the most common causes of lateral curvature. Here proper gymnastics are indicated, but they should be prescribed and carried out with much care. In cases of gravity, the children are unable to bear much exercise without fatigue. Those exercises, therefore, chiefly needed in correcting the deformity, should be the only ones prescribed. The usual class-work of the gymnasia is to be avoided, as such cases require the individual attention of a competent person, who will see that no faulty position is taken during the exercises.

Mr. Bernard Roth, of London, has devoted much time and attention to the development of proper simple gymnastics, combined with postural treatment, the efficiency of which he has demonstrated by a series of successful cases. He has pointed out that in each individual a certain attitude can be voluntarily assumed by the patient, which is the nearest approach to the normal. This attitude varies to a degree in each case. The first step in treatment should be to determine this position, which he calls the "key-note" position. All exercises should be made in such a way as to develop the muscles involved in this attitude, or while the attitude is maintained. The following are the exercises which he prescribes, varying in a measure in individual cases: —

(1) Lying on the back, arms by the side, hands supinated, very slow, deep inspirations by the nose, expirations by the mouth.

(2) The same, with arms extended above the head.

(3) Position the same as No. 1, head rotation, lateral flexion of head.

(4) Position the same, simultaneous circumduction of both shoulder-joints from before backwards, elbows and wrists extended.

(5) Position the same, one hip circumducted both ways (knees extended).

(6) Lying on back, simultaneous extension of both arms upwards, outwards, downwards, from a position of the elbows flexed and close to the trunk.

(7) Lying prone, one hip circumducted both ways, knee kept extended.

(8) Sitting on a couch, with the back at an angle of 45°, ankle circumducted in, up and out, while the toes are inward the whole time.

(9) Lying on back, with arms extended upwards by the sides of the head, flexion of both arms (surgeon resisting). (The patient's knees, flexed over the ends of the table, fix the trunk.)

(10) Patient astride a narrow table, with the arms down and hands supinated, trunk-flexion at lumbar vertebræ (patient resisting), followed by trunk extension (surgeon resisting).

(11) Patient, with arms extended upwards, leans against a vertical post with pegs on each side; these he grasps. The surgeon gently pulls the patient's pelvis forward by his hands on the sacrum (patient resisting), also pelvis rotation on its axis to right and left alternately (surgeon resisting), with the hands on each side of the pelvis.

(12) Lying on back, with head and neck projecting beyond the end of table, the head is gently flexed by the surgeon's hand on occiput (patient resisting).[5]

One merit of the method of posture and exercise is its simplicity and ready applicability by every practitioner. There is great danger of making the matter appear unduly complicated, and this is the case if an attempt be made to differentiate the different bellies of the individual muscles, on the convexity of the different curves. The fact of the matter is that the curves are the result of static laws, and that the muscles are only at fault in so far as they do not hold the trunk erect, and thus allow the superincumbent weight to fall unequally. The muscles chiefly engaged in keeping the trunk erect are the large ones of the back, the latissimus dorsi, with the trapezius and the erector-spinæ.

It is not a difficult matter to devise simple and practicable exercises to develop these back muscles. The strength of a patient's back muscles can be determined in a ready way by attaching a cord to the front of a cap tied to the head, and fastening this cord to a spring balance. The patient, seated at the proper distance from the spring balance, held firmly by an assistant, is directed to bend backwards, keeping the back straight so far as is possible, and the amount of the pull is indicated upon the dial.[6] A record of this registers any increase in the strength of the patient, and as a clinical fact, it will be found that an improvement in carriage will correspond to an improvement in the indicated strength.

The round shoulders of growing children present a typical illustration of what is termed flexible curves (Fig. 5). The deformity is clearly an exaggeration of the normal physiological curve, and due to muscular weakness of the muscles, which would hold the head erect, to which is usually added a lack of tone of the muscles holding the scapulæ back, namely, the trapezius serratus.

Fig. 5.

Round shoulders may also be secondary to the curve in the hollow of the back, lordosis, that is, the arching back of the body, which is seen in the effort to rest the spinal muscles, weak from any cause, by balancing the weight of the trunk. This is particularly noticeable in Duchenne's paralysis.

Scoliosis, lateral curvature proper, is not due primarily to muscular weakness, but as has been shown, is the secondary result of a back imperfectly supported and of improper attitudes, which are due frequently to muscular weakness, which latter presents a rational indication for treatment.

[5] British Medical Journal, May 13, 1882; and also Walsham, St. Bartholomew's Hospital Reports, Vol. XX, 195.

[6] By fastening a spring balance to the wall, and an arrangement with pulleys and cord connected to straps fastened to the patient, the actual amount of force in different movements can be estimated.

The management of cases of this sort may be described in a general way as follows:

After a careful inspection of the deformity, diagnosis as to the flexibility of the curves, and examination of the faulty attitudes, the child's height and weight should be taken, and a comparison made with the standards established by Bowditch's tables, in order to determine whether any excess of growth in height or deficiency in weight existed. It should be considered that if a child has grown with unusual rapidity, or if the height had increased without a proportionate increase of weight, greater care should be exercised in the management of the case. The patient should then be directed and taught to sit and stand and walk in as nearly a normal position as possible, and be drilled to assume this position. It should be the object of the attendant to see that all exercises taken during the exercise hour should be done without an assumption of a faulty attitude. The exercises assigned should vary in each case. In addition to those already mentioned, the following will be found of use:

(1) The patient sits facing the assistant who holds a strap passing about the patient's occiput (prevented from slipping by a cross strap around head and chin). The patient bends forward and back, keeping the spine straight. The backward movement is resisted by the assistant.

(2) Same as above, except the straps cross the shoulders.

These exercises may be carried on with a weight and pulley, or rubber exercising tubes instead of the resistance of the assistant, but the amount of force is less readily regulated. The assistant should correct any arching of the back.

(3) The patient stands facing a wall at arm's length from it; places the left hand upon the wall at the height of the chin, the hand being in a direction across the body. The patient, supported by the arm, slowly brings the face towards the arm, bending at the ankles, keeping the whole body in line; the face should be turned so that the left ear touches the hand, and the standing position slowly resumed, the body being still kept from bending at the hips.

(4) The patient stands with the heels, back and occiput against a projecting corner (of furniture or doorway), and places the elbow (the arm being flexed) as far back as possible.

(5) The patient, seated on a stool or chair, should place the feet behind, and on the inner side of, the front legs of the chair, and slowly bend sideways; the assistant, resisting on the head, determines the strain on the muscles of either side.

For children accustomed to stand upon one leg, the best exercise is to drill them to stand upon the other for a specified number of minutes, and standing on one leg to lower and raise the body, bending at the knee.

In almost all flexible cases, and in a majority of cases with commencing osseous curves, all the treatment that is required is postural or gymnastic, thoroughly carried out. In certain cases of this class, and in most of the severer cases, treatment by some mechanical aid is needed. This help is indicated in curves which may be considered as threatening, even if flexible, for gymnastics and postural supervisions are only possible for a limited time during the day, and it is desirable in such cases that at no time should faulty positions be assumed. It should, however, always be borne in mind that mechanical supports are injurious in so far as they take the place of muscular support, and therefore defeat the object to be arrived at in an ultimate cure. They should never be used to the exclusion of gymnastics.

A great variety of spinal supports, corsets and appliances for this purpose have been devised. The chief defects of most of these are that besides being cumbersome, they are not fixed in their bearing upon the pelvis, and allow the patient to lean to the side and to assume faulty positions.

If a patient with a flexible lateral curvature be examined, it will be found that in endeavoring to push the spine straight, pressure will be exerted on the right side of the back, a little below and behind the axilla, and counter pressure in the front of the trunk, upon the pelvis, just below the anterior superior spine (Fig. 6). It will also be necessary in some cases to

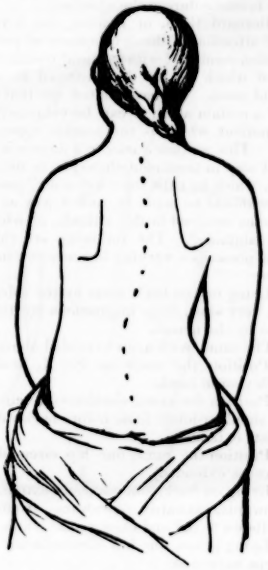

FIG. 6.

push the right shoulder down, and to pull back the right shoulder blade. Sometimes also it is desirable to push up the left shoulder. These points vary necessarily in different cases, but in the typical lateral curvature with the upper convexity to the left, they are as here indicated. Mechanical support and pressure should therefore be in this direction, and as far as possible there should be no support or pressure at any other place, and motion in every other way should not be limited, that free play of the muscles be allowed for their development.

In cases of pronounced fixed curves with marked change in bone, the matter is a different one. This condition of the spinal column is readily recognized by the fact, that the curves do not diminish when the patient is recumbent or suspended, and that rotation

is indicated by projection of the ribs when the patient bends forward (Fig. 7).

In these cases a cure that is a complete correction of the deformity is not to be hoped for; in some severe cases an arrest of the increasing curves is difficult, and all that can be done is to relieve the symptoms presented, as far as is possible. In many of these cases, plaster corsets, applied with the aid of suspension, are of assistance; or better, leather glue or silicate corsets, made from casts of the trunk in an improved condition, are of great help. Ordinary stiff corsets, or any support which constricts and steadies the trunk, will often relieve the symptoms of pain in aggravated cases.

Some of these cases are also relieved by gymnastic exercises, massage and electricity.

Two errors of prognosis are common in regard to lateral curvature:

(1) To regard the affection as of little moment, and likely to correct itself.

(2) That the affection is one of immediate gravity.

The latter view is less frequently entertained, and

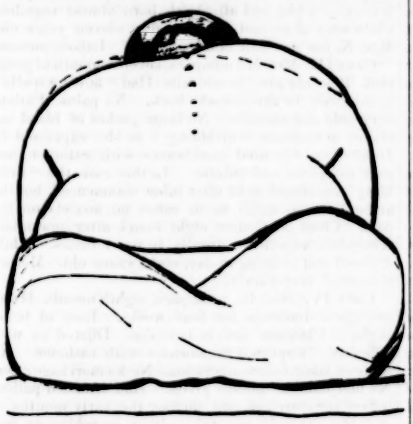

Fig. 7.

is due to a confusion of the disease with caries of the spine, but the former error is quite wide spread.

In a majority of cases of scoliosis, the curvature becomes self-limited, and a slight twist of the spine is of no great importance. This may be said of most of the diseases of childhood, but it is impossible to predict that an increase of the curvature may not take place in any given case. It is certain that no spontaneous rectification of a pronounced lateral curvature has ever been observed, while a progressive increase to a stage of permanent and incurable disability is, unfortunately, not rare. Instances are occasionally seen where a curve which has occasioned little or no trouble during girlhood and early womanhood, increases and gives rise to much discomfort after middle life. It may therefore be said that every patient with a laterally curved spine, even if not suffering from the deformity, is in danger from it of discomfort and partial disability, and that the danger is the greater the poorer the patient's health and strength.

The subject may be summed briefly as follows:

Of the two chief factors determining lateral curvature, superincumbent weight and faulty attitudes, the latter in the early stages of disease is the one which offers feasible indications for continuous treatment.

Faulty attitudes can be corrected by properly directed gymnastics and by drill.

After pronounced osseous curves have been formed, a complete correction is difficult or impossible.

Gymnastics are of great help in correcting any tendency to increase of the deformity.

The gymnastics should be carefully prescribed and efficiently carried out daily.

Proper appliances may be required, but they should be regarded as an adjuvant to gymnastics, and as a means of retention in severe cases.

The affection is one which is easily prevented, but cured with difficulty, and treatment cannot be begun too early.

A METHOD OF TREATING PLACENTA PREVIA, SOME POINTS OF WHICH ARE NOT TO BE FOUND IN THE STANDARD WORKS ON MIDWIFERY.

BY PHANUEL E. BISHOP M. D., PAWTUCKET, R. I.

Doubtless every physician at the commencement of his practice, has looked forward with great concern to his first case of placenta previa.

When we consider the great danger to both mother and child, and the hopes and fears of the medical attendant, all cases become formidable even to obstetricians of skill and experience. Taking it for granted that every practitioner is familiar with past and present literature upon this interesting subject, I will omit from this paper all that is usually found in standard works upon obstetrics.

Very early in my practice, some thirteen years ago, my first case of placenta previa occurred. A physician of large experience saw the case with me, and confirmed my diagnosis. The method of treatment then discussed was strictly adhered to in this and seven other cases which have since occurred in my practice, or been seen in consultation.

On account of this experience, and the uniform success attending each one, I deem it my duty to present this paper to the public.

The above mentioned method of treatment can be best described by reporting my last case in detail.

On May 16th, 5 P.M., I was called to attend Mrs. B. who had nearly completed the seventh month of her fourth pregnancy. She was under my

care during her last two confinements which were normal in every respect. While quietly sitting in a chair, without any pain or other warning whatever, a profuse hemorrhage from the vagina occurred, which continued about ten minutes. It had nearly ceased upon my arrival. No examination was made at this time. She was put to bed and the precautions taken which are customary in cases of accidental or unavoidable ante-partum hemorrhage. At 10 P.M., I was called again. Another gush had taken place at 9 o'clock, which had now ceased. An examination was now made. After removing a small clot, the os and cervix were carefully examined by both touch and speculum. There was little or no dilatation of the former or obliteration of the latter. I did not try to pass my finger into the cavity of the uterus. Strongly suspecting placenta previa, the possibilities and probabilities of the case were frankly stated to the patient and family, and the former cheered up, and assured that I would safely take her through her peril. Deeming it my duty to remain for the present, I gave Mrs. B. a full dose of morphine combined with atropine, and lay down for a nap, leaving orders to be called immediately should flowing occur. In the morning I left her quietly sleeping. No hemorrhage during the night. Saw her at noon. Found her very comfortable, encouraged her, and promised to call the next day. Was summoned again the same evening at 10 o'clock. Hemorrhage quite brisk, pulse rapid, great restlessness and other symptoms alarming. I decided to do my duty at once, namely, *empty the womb and save my patient's life.* One grain of morphine combined with one-fiftieth of a grain of atropine was now put under the skin; thirty grains bisulphate quinine administered in wafer paper; the urine drawn, and the following enema given: spts. turpentine, one ounce; castor oil, two ounces; yolks of two eggs; castile soap suds, one quart thoroughly mixed. After the enema had operated, the patient was placed upon her back in the usual position for instrumental delivery. One hand was passed into the vagina, the first finger of which was gently but firmly carried into the womb, dilating the os as I proceeded. My fears were now confirmed. I was dealing with a case of placenta previa centralis. Continuing to dilate gently and rapidly until two fingers could be easily passed, I soon had the placenta separated from one side for quite a space, as far up as my fingers would reach. Taking a silver male catheter, No. 18 American scale, I now passed the curve into the uterus between the placenta and my fingers until it reached the tips of the latter. Then with a gentle rocking motion, it was carried still higher, separating the placenta as it advanced, until the upper margin of the same was passed and the membranes reached. These were now easily and thoroughly ruptured and the liquor amnii allowed to escape. Mrs. B. now received a copious douche of hot water, had her linen changed, and was placed in a clean, dry bed, in order to get a little rest before labor should commence, which I knew would not be long delayed. She went to sleep almost immediately, the pulse and respirations assuming a better character directly. After watching her for half an hour, during which time not one drop of blood escaped, I lay down to get a little rest myself. It was now midnight. I was awakened at 3.30 A.M. Pains commenced at 3. Child and placenta born almost simultaneously at 5. Child born alive premature and feeble, and lived only a few hours. Mrs. B. received a good generous diet, with Wine of Coca ad libitum. She arose on the tenth day feeling well but rather anæmic. With the exception of bisulphate quinine twice daily, she required no medicine. I will now briefly notice the other seven cases.

CASE I. Mrs. J., multipara, second child. Placenta previa lateralis. Catheter used, morphine and quinine exhibited. No pains before operation. Labor commenced half an hour afterwards. Child born dead about an hour later. Afterbirth removed with the hand. Have attended her three times since. Confinements normal.

CASE II. Mrs. N., tertipara, eighth month. Placenta prævia lateralis. Had slight hæmorrhages at different times for the past two months. Labor had commenced before my arrival. Flowing profuse, pains weak. Patient pulseless, and well-nigh bloodless. Ruptured membranes with finger. Morphine and quinine exhibited in large doses at once. Hæmorrhage ceased immediately. Pains frequent, sharp and decisive. Child and afterbirth born almost together. Child born alive, and living to-day, eleven years old. Mrs. N. has had four children since. Labors normal.

CASE III. Mrs. M., nonipara, seventh month of gestation. Placenta prævia centralis. Had "flowing spells" at intervals for three weeks back. No pains. Patient very pale and anæmic. No large gushes of blood but almost a constant "dribbling" as she expressed it. Dilated os, ruptured membranes with catheter, and gave morphine and quinine. In this case the "dribbling" continued until after labor commenced, but the amount was so small as to cause no anxiety on my part. Child born alive eight hours after operation. Afterbirth expelled naturally in ten minutes. Child did well and is living to-day, eight years old. Mother recovered very slowly.

CASE IV. Mrs. D., primipara, eighth month. Hæmorrhage at intervals for four weeks. Loss of blood slight. Placenta prævia lateralis. Dilated os with difficulty. Ruptured membranes with catheter. No signs of labor before operation. No hæmorrhage after. No morphine or quinine given. Had attended patient before her marriage and during the early months of gestation. Could not take either morphine or quinine. Labor delayed two days. Child born with forceps fifteen hours afterwards. Child did well. Mother had mammary abscess which greatly retarded her recovery. Attended her once since. No trouble.

CASE V. Mrs. A., tertipara, eighth month. Placenta prævia lateralis. Slight hæmorrhage at intervals for six weeks. In bed about all the time. Tried to carry her through to full term. Hæmorrhage suddenly becoming very alarming, and no pains, I proceeded as in Case III. Labor terminated two hours after operation. Child dead born. Mother had phlegmasia dolens. Recovery slow. Have attended her twice since. She died of phthisis six months ago one year after birth of last child, and seven years after birth of third.

CASE VI. Mrs. C., nonipara, seventh month. Placenta prævia centralis. Had been "unwell" every month since becoming pregnant. Had lost more blood than common, especially at the last two periods. Labor had commenced before I was called. Hæmorrhage steady and severe since pains began. I proceeded as in Case III. Child born alive one hour

afterwards, and lived eight hours. Mother made an excellent recovery.

Case VII. Mrs. M., multipara, third child, between six and seventh month. Was seized with hæmorrhage while out riding. She was taken home, and I attended her for accidental hæmorrhage for one week, at the end of which I made a thorough examination. Placenta prævia centralis. No pains, although the os was very soft and easily dilated. Proposed delivering her at once. Patient and family refused my proposition, as I told them the child would probably be born dead or live but a short time after its birth. I requested my dismission from the case which was granted. Saw her again in four days. Operated at once in order to save patient's life, which was in great jeopardy. Family not so anxious now as they were four days before concerning welfare of child. Conducted this case precisely like No. VIII, which is reported in detail. Child dead-born. Mother did well, far better than I thought she would.

I will close this paper with the following remarks: As it seems to me the first thing to work for, in treating placenta prævia by the above method is to secure the entire confidence of both patient and family. Perform the operation without anæsthetics if possible, for they both favor hæmorrhage and take away from the pains that force which we are so anxious to secure. Have nothing whatever to do with ergot. It is worse than useless. We never can tell how it will act. It is liable to cause the os to contract and lock every thing up just when we want to keep it open so that we can empty the womb. Don't bother with the tampon. It cannot do any harm when introduced properly, but will do little or no good, and then again we are wasting precious time. What we want, is no hæmorrhage and good effective pains. Can we secure these? I answer emphatically and without hesitation, yes. Separate the placenta from one side as far as possible. If the os is not open, dilate. Rupture the membranes thoroughly. You have now fulfilled the first indication. Morphine and quinine in large doses have in my hands always fulfilled the second. A woman lies at death's door from ante-partum hæmorrhage. There is nothing like a full dose of morphine to help her rally and get a fresh grip on life. Bedford says: "Be not afraid of this remedy, it is the sheet-anchor of hope in cases in which the patient is almost sinking from exhaustion consequent upon profuse hæmorrhage." It is also oxytocic. Narcotism is almost impossible. It is well enough to combine atropine as has always been my custom. Experience has taught me that quinine in large doses *is the oxytocic* par excellence. I have used it thus in a great many cases. In my hands it almost never fails to produce just such pains as are required. Then, again, it wards off chills, acts as a tonic and prevents septicæmia.

— An American ward of the Guild of S. Luke, Evangelist and Physician, has been recently formed in Rhode Island, Dr. W. Thornton Parker, Provost.

— The papers that hoist before the public the figures of their circulation — apt to be fathomless lies — bear the same relation, remarks a lay contemporary, to admirable journalism that John L. Sullivan, whose circulation is much greater than Oliver Wendell Holmes's, bears to that intellectual autocrat.

REPORT ON PROGRESS IN SURGERY.[1]

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

END RESULT OF CARCINOMA OF THE LIP AFTER OPERATION.

A. Wörner[2] has collected and tabulated 866 cases from Brun, Thiersch, von Bergmann, Billroth, Winniwarter, Fischer, Kocher and Partsche. His results show that

782 cases (90.4%) were in men.
84 " (9.6%) " " women.
— " (94.4%) " " under lip.
— " (5.6%) " " upper "

The average mortality was 7 per cent.; the minimum being 2.81 per cent.; the maximum 14.9 per cent., both of which results were obtained from data of the preantiseptic period. Permanent recovery occurred in 28.1 per cent., but among all cases of recurrence 87.6 per cent. occurred within one year after the operation, and cases which had escaped without recurrence for three years could, with great certainty, be considered cured. Wörner mentions one case where a secondary operation was performed nine years after the primary one, the patient surviving eleven years without recurrence.

OPERATIVE TREATMENT OF FRACTURE OF THE PATELLA.

The operative methods now in vogue are:

(1) Evacuation of articulative effusion by aspiration or puncture.

(2) Tendon ligature. (Volkmann.)

(3) Bone suture. Introduced by Lister in 1877, either open or subcutaneous, the most recent plan of which is that of Ceci.[3]

(4) Malgaigne's Hooks.

(5) Morton's Method.

Dr. Conrad Brunner,[4] of Zurich, has recently published an exhaustive and carefully-written article intended to show the comparative value of simple and operative treatment of fractures of the patella The data from which he has formed his conclusions consist of detailed histories of forty-four cases treated by the former method and statistical tables containing the essential points in ninety cases of fracture treated by suture.

The operative method being a comparatively modern procedure the final results cannot be so fully learned as those of the older plan. However, the results, as far as can be obtained, show that the opening of a knee-joint to suture a patella is entirely unjustifiable in the great majority of cases. Brunner finds that the simple method gives practically as good results and hence concludes that there is no real necessity for the operation, for the primary object of treatment is in his opinion to restore the function of the limb and not to secure bony union. And in regard to this point the operative method cannot show any better results than those obtained after the older method. Since among the cases operated upon records exist of eight cases of suppuration, two requiring subsequent amputation of the thigh, nine resulting in anchylosis, and three deaths. It can scarcely be regarded as a

[1] Concluded from p. 190.
[2] Centralblatt für Chir., No. 25, 1886, s. 432.
[3] Eine neue Operation der Patellar Fracture. Subcutane Metallnaht der Kniescheibe. Deutsche Zeitschrift f. Chirurg. Bd. xxiii, Heft. 3-4.
[4] Ueber Behandlung und Endresultate der Querbrüche der Patella. Deutsche. Zeitschrift für Chirurg. Bd. xxiii, Heft, 1-2.

method of treatment unattended by danger, and the danger thus incurred by the patient is not compensated for by a better functional result than can be obtained by a simpler method devoid of risk.

Chauvel [5] has reported forty-three cases with severe arthritis in twenty; 120 amputations and three deaths.

According to the final results now on record it seems to be unwarrantable to transform a simple fracture into a compound one, to secure bony union which does not give the patient a better functional result than is obtained in a case of ligamentous uniting of the fragments. The claim that the duration of treatment is shortened is not supported by statistics.

The conclusions to be drawn from the above are that all cases of this injury should be treated by the "simple" method, except when a free communication with the fracture already exists or where a badly united fracture or useless limb demands a more effectual treatment.

DISLOCATIONS OF THE SHOULDER.

Neil Macleod [6] describes what he terms "a new, easy, rapid and painless method of reduction of dislocations of the shoulder, without an anæsthetic," in the following terms: Let the patient lie down on his back on the floor, with the dislocated arm outstretched at right angles to the trunk, and also on the floor. Having told the patient to lie quite still and make no effort, let the surgeon, placing the approximate heel in the axilla, make traction gently and steadily at right angles to the line of the trunk; and, as there may be no jerk or evident intimation of the return of the head of the bone to its place, let him ascertain its position, if necessary, adducting the limb to make sure. This method it is claimed is painless.

TRANSPLANTATION OF BONE.

Ferrari [7] arrives at the following conclusions: That pieces of bone inserted in the diaphyses of long bones may become completely united to them, and continue to live and grow. The re-union of grafting takes place by a true vascularization, which forms between the piece inserted and that to which it is applied. Around the piece inserted, a bony, peritosteal, and medullary callus is formed, which has only a temporary vitality, and after the lapse of time the callus is absorbed and the engrafted bone can only be recognized by its greater vascularity. Complete antisepsis is essential to success. A favorable result is obtained even when the smallest pieces are inserted. Moderate pressure should be used on the engrafted bone to maintain contact between the medulla and the piece of bone transplanted.

DIAGNOSIS OF INJURIES TO THE SACRO-ILIAC ARTICULATION.

Lewis [8] calls attention to the liability of overlooking injuries to the sacro-iliac articulation. He considers the following to be the principal points in diagnosticating this injury. The history of the injury. Any force which rotates the pelvis under severe pressure, or any force which acts as a wedge between the sacrum and innominate bone, is liable to injure the sacro-iliac articulation, although it does not cause separation and deformity. The symptoms are usually associated with those of contusion of the hip, but differ in this, that the patient must lie on the back for a long period of time, the slightest lateral pressure on the pelvis being unbearable. The patient is able to be assisted to the erect posture and to move about on crutches for some time before being able to lie on either side. Many months elapse before the patient can walk with ease, and frequently the injury is permanent to the extent of rendering him unable to do any active work. The walking is peculiar, the uninjured side being used as a pivot on which to swing the pelvis, and thus save strain on the affected articulation. Dr. Lewis cites two illustrative cases of this injury.

INTRA-CRANIAL TUMORS.

The Pathological Society of London, in February, held a special meeting for the exhibition and consideration of intra-cranial tumors.[9] From a surgical standpoint, the meeting was of interest, as there was a large number of tumors exhibited, and "they illustrated the tendency of cortical gliomata to remain limited to the gray matter, and the opposite infiltrating characters of these tumors in the white substance; the rarity with which it is possible to localize with certainty the site of tumors; the difficulty of determining their size, and the extent to which they infiltrate their surroundings; the vast variety of clinical phenomena, and the variations in their anatomical and histological structure."

Dr. Goodhart considered that the number of tumors which could be removed with any probability of success was very limited.

DISINFECTION OF HANDS.

Kümmel,[10] of Hamburg, has performed an elaborate series of experiments to ascertain the best method of making a surgeon's hands absolutely aseptic. He found that contact with soiled dressings, or at autopsies, rendered this result more difficult. Sublimate, one-tenth per cent., was inefficient. The following conditions are necessary for satisfactory disinfection of hands:

(1) Five minutes' vigorous or thorough scrubbing with brush, soap, and water, as hot as can be borne.

(2) A thorough two minutes' brushing of the hands in freshly-prepared officinal chlorine water or carbolic solution, five per cent.

In operating, the fore-arm should be cleaned, as well as the hand.

REMOVAL OF MOLES AND WARTS BY ELECTROLYSIS.

Voltolini [11] uses a battery of five elements. Two kinds of needles can be used, one of platinum, the other of steel. The latter needle is intended for very hard warts, and must be attached to the negative pole to avoid oxidation. Moles and warts must be soaked in water. The needles must never be introduced deeper than the level of the skin, nor be allowed to touch one another. The action of the galvanic current may be continued from five to ten minutes at most, the needle being pushed in different directions, whilst water is allowed to drop on to the part operated on. In from two to four minutes, the substance of moderately soft warts become pulpy. This is the indication for the operation to stop. This pulp dries up, becomes black, and in a week or fortnight falls off.

TOTAL EXTIRPATION OF THE SCAPULA.

Shutz [12] has recently published the result of a case of complete removal of the scapula, the acromial end of the clavicle, and the head of the humerus for extensive caries. The result is a useful arm. His review of the subject has resulted in a collection of twelve cases, of which six (fifty per cent.) show a favorable result; two deaths, two failures (loss of arm from gangrene); two cases result not known.

Gies [13] published in 1880, a table containing eleven cases, in which the complete extirpation of the scapula, and simultaneous removal of the head of the humerus was performed. The causes for operation — caries, necrosis, fractures, gun-shot injuries, enchondroma, osteochondroma, and cancer. The results show four deaths, three within ten days, one from recurrence; four complete recoveries; one case with favorable result at end of three months; two, result not given.

AMPUTATION AT THE KNEE-JOINT BY DISARTICULATION.

In an interesting discussion at the Royal Medical and Chirurgical Society, following a paper on this subject by Mr. Bryant,[14] the following views were expressed. Mr. Bryant considered the operation of disarticulation required for its success that the disease or injury should be confined to the leg, that the condyles of the femur be involved, or very slightly affected, and that there is a sufficiency of healthy soft parts below the knee for the formation of a good stump. The cicatrix was always placed well behind the femur. The patella was preserved, its removal being found quite unnecessary. Of the three different methods of operating, namely, that of Pollock by the long anterior flap, Pick's plan by lateral flaps, and Stephen Smith's method by lateral hooded flaps, Mr. Bryant preferred Smith's method. He gave tables of thirty cases, with the results. He considered that the leaving of the semilunar cartilages *in situ* was a great advantage. The advantages of this form of operation he summarized as follows:

First. The lessened shock of operation.

Second. The lessened section of tissues, and the non-exposure of the muscular interspaces of the thigh.

Third. The escape from the necessity of sawing the femur, with attendant risks.

Fourth. The preservation of the attachments of the thigh muscles, and consequently, the greater mobility of the stump.

Fifth. The useful character of the resulting stump.

Sloughing of the flaps was considered by many of the speakers to be quite common. Early and efficient drainage for the first days was considered to be very important, for sometimes much synovial fluid was secreted.

RUPTURE OF THE LIGAMENTUM PATELLÆ.

This comparatively rare injury is considered by Henry B. Sands [15] in a paper based upon the observation of thirteen cases. He advocates a departure in our treatment of this injury from the use of mechanical apparatus designed either to prevent the knee from being bent or, to make an artificial extension by elastic force. In two cases he has operated and united the ligament and it will be of interest to record his method of procedure. A longitudinal incision, six inches in length, was made in the median line on the anterior aspect of the knee, the centre of the incision being opposite the lower edge of the patella. The cut was subsequently lengthened both upward and downward to nine inches. On exposing the injured parts, in doing which the knee-joint was freely opened, it was found that the ligamentum patellæ had been torn away from the spine of the tibia, which was now covered by only a small amount of dense fibrous tissue, sufficient, nevertheless, to allow a firm hold for sutures. A little more than an inch of the ligament in good condition, was normally attached to the patella. Before the upper end could be drawn down and placed in contact with the lower one, it became necessary to make many deep oblique and transverse incisions into the median and lateral portions of the quadriceps; and even when this had been done as far as was deemed prudent, considerable force was required to secure apposition, which was maintained by two sutures of stout silver wire. The mucous and alvar ligaments were found redundant, and were partly removed with curved scissors. The incisions in the capsule of the joint were closed by catgut sutures, and the external wound was united, except at its upper and lower ends, in the same manner. Two bone drains, one on each side, were inserted into the joint through openings made for that purpose, and one into each extremity of the median incision.

Antiseptic precautions were observed. The first four days the patient complained of pain, this was so severe that on the second day the dressing was removed and the wound was examined The drainage-tubes were cleaned of a few clots of blood, and a fresh dressing was applied. The pain after the fourth day gradually diminished and finally disappeared. At the end of seven weeks the wound was found healed, the patella movable, as was also the knee-joint. Two weeks later the patient was allowed to get up with a water-glass bandage. At the end of five months the bandage and the splint was laid aside and the knee had assumed nearly its natural size, the continuity of the ruptured parts having been reëstablished. A table of cases concludes the article.

RUPTURE OF TENDONS. TREATMENT OF DIVIDED TENDONS.

Hagar [16] has operated for a so-called spontaneous rupture of the tendon of the extensor of the longus pollicis thumb. An exploratory incision was made for the purpose of finding the divided end. Failing to discover the proximal end (on account of retraction) the distal end was cut obliquely and sutured by catgut to the tendon of the extensor indicis after opening the sheath of the latter and denuding a suitable surface by scraping of the epithelium. Under antiseptic treatment primary union followed. The operation was performed seventeen days after the occurrence of the lesion. In two months after operation extension of the thumb was nearly restored and in six months the movements of the hand were nearly normal.

Reports of Societies.

NEW YORK COUNTY MEDICAL ASSOCIATION.

STATED meeting, June 21, 1886.

DR. EDWARD G. JANEWAY read a paper on

CERTAIN POINTS IN THE DIAGNOSIS OF SOME OF THE INFECTIOUS DISEASES.

The subject, he said, was one which did not have the merit of novelty, and although it had been suggested to him by the President of the Association, he would not have ventured to present it had it not been that for a number of years he was so placed (as one of the Health Commissioners of the city of New York) that it was necessary to give a great deal of attention to the matter, and that he was, moreover, enabled to see those circumstances which were most likely to lead to erroneous opinions, and at times to witness the sad effect of some of these.

The diagnosis of small-pox, when it presented itself with all its usual features was a matter of no special difficulty to one who had seen even a few cases; but students of medicine in this country had, unfortunately, owing to the stringent isolation and quarantining laws, but little opportunity to become acquainted with the ordinary physiogomy of this complaint. Besides, owing to the system of persuasive vaccination carried on in the city of New York, and presumably to somewhat the same extent in other cities of the country, for nine or ten years there had been comparatively little of the disease. Systematic vaccination in general, vaccination in the neighborhood where a case of small-pox had occurred, isolation or removal of the patient, disinfection of premises, and subsequent careful outlook for other cases in the vicinity, had been successful to an extent appreciated by few. But the outlook for the future he did not think so assuring, as the work of vaccination had been crippled to a considerable extent during the past year; and a large contingent of unprotected persons existed, who might become victims to, and spreaders of the disease.

Dr. Janeway had known the start of a considerable outbreak of small-pox to be traced to a single erroneous opinion. Another very unfortunate circumstance had happened which would tend to delay the prompt action desirable in dealing with the disease. The law had been invoked to inflict a penalty upon a physician who had reported a case of suspected small-pox to the Board of Health, and though an appeal had been taken which would probably be successful, yet the effect was unfortunate. It seemed to him that the case of the physician dealing with disease, and particularly with one which was dangerous to the public health, ought to be protected by law.

One of the greatest safeguards against an error of diagnosis as regards small-pox consisted in having such a classification of the disease fixed in the mind as should serve to take account of the various methods of its manifestation. In a number of the text-books important facts bearing upon the method of development of certain forms of small-pox were omitted. A satisfactory classification he had found as follows:

Purpura variolosa.
Variola-vera. Confluent.
" Semi-confluent.
" Discrete.
" Corrymbose.
" Hæmorrhagic.
Varioloid.
" Variola Varicelloidis.

The distinction between purpura variolosa and the ordinary hæmorrhagic type, where the blood is extravasated into the vesicles, should be kept in mind, and it could be best accomplished, he believed, by making such a classification as the one referred to. In his experience the failure to recognize, or even to have any knowledge of the existence of this form of the disease had led to very serious consequences. The danger consisted in mistakes between this form of the disease and the malignant type of some of the other infectious diseases, particularly measles, and, much more rarely, typhus fever, ulcerative endocarditis, and purpura hæmorrhagica.

A careful cross-examination of the patient and his friends should be made, and at the same time the possibility taken into consideration that a visit to a strange place, the getting of new clothing, etc., might in the absence of any other clue furnish one. In these days of rapid travel, with emigration to the West in that section of the country, as well as here, the recent arrival of strangers in the neighborhood should be thought of. Should it be learned that a possible ex-

posure had happened, and to a case of disease of unknown nature, it should be a part of our duty to ascertain by inspection of such sick person or by inquiring of the physician in attendance the nature of the illness.

By way of illustration Dr. Janeway related the following case: Some years ago he was called in consultation to another city to decide as to the nature of a strange variety of fever. One patient had died of it, and another was seriously ill at the time. When seen, the latter was sitting in bed, with very feeble pulse, though with only slight febrile movement, and showing evidence of dyspnœa, due to changes in the blood. He had a wet cloth on his forehead, which concealed a number of purpuric spots in the skin of that part; while on the chest, abdomen and legs these purpuric spots also existed. In one place there was a small vesicle (which was, however, of no determinate character), and at no point were there any papules or umbilicated vesicles. His mind was perfectly clear, and this was the sixth day of his illness. The hæmorrhages had only appeared in the skin of the forehead on the morning of that day, but the eruption on the rest of the body had already existed for more than twenty-four hours. Dr. Janeway suggested that the disease was in all probability purpura variolosa; in which opinion he received confirmation, *first*, by learning that this patient had attended the one who died, and had held her in his arms, the fatal issue having occurred about twelve days before the beginning of his own sickness; and *second*, by asking about the others who had been exposed during the sickness and at the funeral of the first patient. He learned that a number of these individuals were down with fever, and that one had an eruption, which proved to be discrete small-pox. The two cases with hæmorrhagic extravasation were, then, undoubtedly variola, but of a form which none of the attending physicians had previously encountered.

This case illustrated, better than any words, these three points to be considered in establishing a diagnosis:

First. It is important to know the nature of the disease from which a malignant case, not itself possessing positive features, has developed.

Second. Should the patient have died, this may be done by an investigation of others exposed to the originating case; these having perhaps a milder and more characteristic type of the malady.

Third. The result of exposure to the malignant case may, in some instances, be a proof of the nature of the disease.

In other words, we must take into consideration what gave rise to the disease in question, and what has been produced by it. Even in a large city, and in the case of homeless tramps, a rigid inquiry and cross-examination could do much toward throwing light on these cases. What he wished to emphasize was, that we must not be content to simply consider the eruption and the patient's condition, but must use every means in our power to establish a correct opinion as to the nature of the disease producing this state, which is denominated purpuric or malignant. It was a great mistake to suppose that hæmorrhages from mucous surfaces, a previous diffused scarlatinal-like rash, or maculo-papules becoming flattened purpuric spots, are necessary accompaniments of this type of hæmorrhagic variola. Variations from this form which he had described were met with, up to that in which characteristic spots of small-pox eruption occurred. Dr. Janeway here introduced another case to illustrate the necessity at times of making an autopsy to decide the nature of a doubtful disease. It was one in which an irregular case of small-pox was mistaken by the attending physician for cerebro-spinal meningitis; and two weeks after the death of the patient, a gentleman who had been with her during her illness and had refused vaccination subsequently, because he thought the disease was not variola, sickened with, and died of confluent small-pox.

The mistake between scarlatina and small-pox happened in those cases of variola in which a marked red efflorescence first occurred, followed by darker spots and papules, and finally by vesicles. In some cases petechiæ appeared in places, and hæmorrhages followed; and not infrequently, in severe cases, he had seen the vesicles first on the inner sides of the thighs and in the axillary space, the face remaining free. As the throat might be sore at this time, a mistake might occur were the order of events not kept in mind, which was two or three days' sickness, and then the rash and sore throat and mouth, due to the eruption. A mistake which he had known to be made was to consider the vesicles in such a case as sudamina. One point was to be carefully borne in mind, namely, that an examination which left out an inspection of the abdomen and chest, and particularly of the inguinal and axillary regions, would be very apt to lead to a mistaken opinion in the case of a severe infectious disease.

The mistake as regards measles occurred in a two-fold manner. On the one hand, the first stages of the small-pox eruption, prior to the formation of the vesicle, led one who looked hurriedly at a case, and did not consider the invasion symptoms, to speak of measles. The other mistake occurred to one who looked at a severe case having the skin red, and in it a number of dark maculo-papules, together with hæmorrhages of larger extent and hæmorrhages from other places, such as the nose, etc. One who had seen the first stage might have considered it as already shown to be scarlet fever, whereas a little later the numerous papules might lead to the mistake of black measles.

The mistake between syphilitic eruptions and small-pox was generally to consider syphilis as variola, rather than the reverse. Most of such mistakes were dependent upon want of close observation of the whole eruption, and of a consideration of the history of the case. The multiformity of the rash, the condition of the glands, and the duration of the disease would determine, in a large number of cases, the correct diagnosis, to which the history would add confirmatory evidence. Two illustrative cases were given by Dr. Janeway. One additional point had been observed, namely, absence of the eruption on the hands and feet and in the mouth in cases of a syphilitic pustular eruption otherwise pretty generally distributed over the body. In his experience, syphilis caused more mistakes in diagnosis than any other disease, excepting only measles.

Mistakes between variola and varicella were not infrequently made. The distinction of typical cases was sufficiently easy, though he thought students were not infrequently puzzled by finding opposing statements regarding the appearance of the varicellous eruption, not only in different text-books, but sometimes, also, in different parts of the same work. The danger in mistaking varicella for varioloid was in paying too close

attention to the eruption, for sometimes a slight induration was met with at the base of some of the spots of varicella, due to irritation. A careful scrutiny would generally show on the back and buttocks, as well as behind the ears, characteristic spots, whilst in other places the eruption might be more or less altered.

In doubtful cases between variola and varicella, attention should be paid to the cause of the attack, if known, and to the time of the development of the eruption after the commencement of sickness. Dr. Janeway had known of several cases of variola being contracted from cases of supposed varicella — cases which had been pronounced varicella by careful and trained examiners. He had met several cases of a varicellous-like eruption, so that he believed in making a subdivision of varioloid which should include this, under the head of variola varicelloides. He was led to this opinion by observing several cases of vesicular eruption closely resembling varicella in persons protected by vaccination, who were in houses where a patient was under treatment for variola. Another chance for error existed in the fact of a patient coming under observation at that time in the history of a mild variola when the vesicle was full.

At times, different forms of skin disease were mistaken for variola, those which were most liable to be thus mistaken being herpes, erythema, urticaria, and lichen.

Typhus fever, when well marked, and presenting the characteristic eruption, occasioned little trouble in making a diagnosis. The earliest cases of a visitation were, however, not always so well developed, and, in consequence, the disease might gain headway, usually in localities most calculated to promote a rapid spread of the disease. In children, particularly, there might be great trouble in deciding between typhoid and typhus. Some years ago, while typhus was prevailing, an outbreak of fever occurred in a certain orphan asylum, where, out of a number sick, there was absolutely no characteristic eruption. The attendants said that only a few had looseness of the bowels; nose-bleed had not been marked, and the records of fever had not been carefully kept; so that it necessitated several days of study before an opinion could be given with some degree of certainty that the disease was typhoid fever. This was confirmed by seven autopsies.

If we were able to study a number of cases, we might find the average duration a marked help in diagnosis, especially in adults. A fever, the great number of cases of which terminated (many of them comparatively suddenly) between the eleventh and fourteenth days, should always raise the suspicion of typhus. An autopsy should invariably be made as a sanitary necessity (should the opportunity occur), to decide the nature of a doubtful outbreak of fever. The lesions of typhoid were characteristic, while those of typhus were in some respects negative; but, in practice, if one of a number of cases of fever which had lasted longer than a week should present, on autopsy, only an enlarged spleen, with minute hæmorrhages on the serous membranes, and parenchymatous degeneration of the liver and kidneys, we should feel justified in considering it due to typhus fever in this climate. Where isolated cases were concerned, an examination of the intestinal mucus and of the muscle should be made, lest the trichinosis disease might have passed as one of the infectious fevers.

Dr. Janeway said he had been much struck by the value of an examination as to the nature of the disease occurring in other inmates of the house or among the friends of a fever patient, as an early help in deciding upon the true cause of a case of fever. The neglect of resorting to this means of information and diagnosis had been in several cases in his experience very unfortunate. As in the case of small-pox, he said he would urge upon the profession the wisdom of oftener resorting to this plan in forming an opinion; and he stated that the Board of Health would do it on request. He was willing to admit that typhoid fever might occur together with typhus; but, in practice, two or more persons, exposed to the same cause of fever, should, if becoming sick with a febrile complaint, notwithstanding certain differences in the manifestations, be considered as having the same disease. He was particular on this point because, owing to some differences in the eruption and certain minor details, he had at times been told that of two members of a family sick, one had typhus, and the other typhoid fever.

It had sometimes been taught that typhoid fever was not contagious, and hence that if several members of a family should sicken one after the other, then if the symptoms were not decisive, this contagious nature would point toward typhus. Taken as a broad generalization of city practice, it might be held true; but, unfortunately enough, exceptions were met with, even in the city, to destroy its full value; while in the country we had the indirect contagion, if not the direct, causing several members of a family successively to fall victims to typhoid. He had known the use of antipyrine to cause the appearance of a profuse, somewhat measly rash, which led the medical attendant to suppose that he had previously considered typhoid to be after all typhus fever. As regards the matter of diarrhœa, all practitioners know that not a few cases of typhoid pass through the disease without it, and, again, that it may occur in typhus, although the passages did not possess the peculiar character of those of typhoid.

Typhus fever was not alone likely to be considered as typhoid, but also to be mistaken for cerebral inflammation, and particularly for cerebro-spinal meningitis, in consequence of the presence of a peculiar petechial rash in the latter. In doubtful cases optic neuritis, if present, would decide in favor of cerebro-spinal inflammation. But, notwithstanding the fact that he had had a considerable experience with cerebro-spinal fever, he had not as yet seen one case the rash in which resembled that of typhus. Moreover, we very frequently meet herpes of the face and lips in cerebro-spinal disease, but so rarely in typhus and typhoid fevers as practically to amount to an almost pathognomonic sign against these affections, if present in a doubtful case. It might occur in so many other conditions, however, that its presence was of no diagnostic value, except as against the probability of either typhus or typhoid.

Flea-bites occurring in typhoid fever had in some instances caused a diagnosis of typhus. So, again, had a profuse rash in which a number of the *taches bilenaties* of the French were present. He had endeavored also to ascertain how far it was probable that pediculi pubis were the cause of this eruption, though without much success.

Tuberculosis was a condition which caused not a few mistakes in the diagnosis of typhoid fever, and, at

times, of typhus also. Meningitis was so rare a complication of typhus or typhoid that its existence should always raise the suspicion of another process, and more particularly of tuberculosis. If under these circumstances choked disc should be found on ophthalmoscopic examination, it would still further increase the probability of this affection. The next step in the diagnosis would be to ascertain if at any point of the body there existed a tubercular lesion accessible to proof or strong suspicion, or if from the previous history there was any probability of such a condition in the lungs. It should be borne in mind that the examination of the lungs in unconscious, and particularly comatose, conditions was extremely unsatisfactory; so that very good examiners had supposed the lungs to be in health when making examinations in those states while in reality they were the seat of far-advanced phthisical processes.

If decided proof should exist, as a result of a physical exploration, that the lungs were the site of disease which from its position could be assumed to be tubercular, then it would, with the foregoing facts, be violence to evidence to call the disease typhus or typhoid, unless absolute proof of the presence of one of these affections could be obtained, as, for instance, by the characteristic eruption of typhus. Some supposed that the finding of bacilli of tubercle in the sputum would invariably decide the question between typhoid and tuberculosis, as, in cases seen moderately late in the disease without a reliable previous history, a broncho-pneumonia of typhoid, and that accompanying certain cases of tuberculosis, might be indistinguishable by physical signs. Provided that the examinations were made with care, and more particularly that every precaution was taken, in collecting the sputum to be certain that there was no contamination of the vessel, nor of the sputum after collection, then the presence of indisputable bacilli would be proof. But— and this was the point to which he particularly wished to direct attention— if it was supposed that any one could make the examination and decide, and if the ordinary manner of collecting sputum were employed, then there were chances for error.

Again, bacilli might not be found in the sputum from tuberculous patients, because of lack of care in selecting the proper portions for examination, and in some cases as a result of employing the short method for staining. While he had been able to make some very good diagnoses by the employment of these means, he had also met cases where phthisis had been diagnosticated as the result of the finding of a few bacilli, yet the subsequent course of the disease or an autopsy disproved the diagnosis. There were certain things which a hasty observer might mistake for bacilli, such as little crystals which appear red as the light is refracted in passing through them, not sufficiently decolorized bacteria of other kinds, etc. Dr. Janeway, however, had seen both typhus and typhoid fever co-existent with phthisis.

Pyæmia, and more particularly that dependent on otitis media and bacterial thrombosis of the lateral sinuses, also caused mistakes in diagnosis, as against typhoid and typhus fever. The reason for this was, that, in the unconscious or delirious state in which patients thus affected were apt to come under observation in hospital practice, no mention was made of the old ear trouble, and no examination of the ear could be made. The irregularity of the fever, the not infrequent co-existence of meningitis or cerebral abscess, with phenomena more or less strongly suggestive of these conditions, the history or the present observation of suppurative discharge from the ear, and that it had perhaps become foul or been arrested, tenderness or œdema over the mastoid process, and the observation of abscesses in the cellular tissue or of joint inflammation, should at once lead to a probable diagnosis of otitis media. The swelling of the little vein behind the ear and the œdema of the tissue over the mastoids might be absent in severe disease, and present when the subsequent course demonstrated that the process was not pyæmia.

In one instance, of a woman with some severe fever, which had been supposed to be typhoid, Dr. Janeway found as a useful adjuvant to diagnosis thrombosis of the internal jugular vein, giving a firm feel to the vessel. During the present year he had met with three illustrations of this malady, and in one the thrombosis of the lateral sinus was not of a completely obstructing nature; so that, in consequence, œdema behind the ear was absent. In a suspected case jaundice would point towards pyæmia or septicæmia, as distinguished from the fevers in which its occurrence was comparatively rare. Such jaundice was present in one of the three cases just referred to.

At the conclusion of his paper Dr. Janeway presented the heart and kidney of a patient who had died of

ULCERATIVE ENDOCARDITIS.

He was a salesman, twenty-seven years of age who had had rheumatism from childhood, and disease of the heart from at least the age of sixteen. The attack in question came on one week before his death. He had a chill, accompanied and followed by headache and pain in the back and shoulder. On the first day the temperature was 103° in the morning, and 104° in the evening. On the next day it was 99° in the morning, and 101° in the evening. On the third day he was affected with muttering delirium, and epistaxis; the morning temperature being 100°, and the evening, 104°. There was, however, no diarrhœa or tympanites.

Fourth day. Temperature, A. M., 102°; P. M., 103⅘°.

Fifth day. Temperature, A. M., 102⅘°; P. M., 104⅘°.

Sixth day. Temperature, A. M., 103; P. M., 104⅘°.

During this time the temperature had been more or less modified by the administration of salicylate of soda and antipyrine. On the seventh day, on which he died, the temperature was 103°.

In this case there was a strong suspicion of typhoid fever, but when the patient was first seen by Dr. Janeway, on the sixth day, he was much more stupid than a case of typhoid fever would have been at that early stage of the disease. On the forehead, behind the ear, and on the back and abdomen, were found a few petechial points. Under the circumstances, he made the diagnosis of ulcerative endocarditis. In addition to a heart-murmur which had previously existed for a long time, a new basic murmur was now detected. On the sixth day, after Dr. Janeway saw him, larger petechiæ or hæmorrhagic extravasations developed on the soles of the feet and palms of the hands.

The specimens presented abundantly confirmed the diagnosis. There had been but one kidney, and this was the seat of numerous hæmorrhagic extravasations.

On the aortic and mitral valves of the heart there were well-marked vegetations. This case, Dr. Janeway remarked, served to illustrate the possibility of mistaking ulcerative endocarditis for some of the more common febrile diseases.

The President, DR. C. A. LEALE, said that within the past three months he had been called to see a child, nine years of age, in whose case four physicians had already failed to make a diagnosis. The symptoms were very obscure, but resembled cerebro-spinal meningitis more than anything else. There was slight opisthotonos, but no eruption of any kind. The child died within forty-eight hours, and no autopsy was permitted.

Within a week, a child residing not more than a hundred yards from the last was taken with similar symptoms. We supposed that it was a case of some suppressed eruption, and ordered the child to be placed in a hot pack. As there was marked exhaustion, alcoholic stimulus was also given freely. Within three days measles became developed, and the patient passed through a violent attack of the measles.

Three years ago he made out the diagnosis of varioloid in the case of a young lady twenty-one years of age. As the attack was a mild one, and there was a possibility of doubt about the nature of the case, he requested that an expert from the Board of Health should be called in, and this gentleman confirmed the diagnosis. Some time later, however, another physician saw the case, and he expressed the opinion that the young lady had had *varicella*, which naturally created a great deal of disturbance. In this connection, Dr. Leale alluded to the great injustice which had been done a well-known New York physician in imposing on him a fine for performing his duty in reporting to the sanitary authorities a suspected case of small-pox.

DR. P. BRYNBERG PORTER called attention to the striking resemblance presented by herpes zoster of the forehead, when at its height, to erysipelas, and the possibility of making a mistake in diagnosis, unless one had seen the case from the beginning, or took special pains to ascertain the exact history of the attack. He related a case in point.

DR. JOHN SHRADY remarked that it was often very difficult to make a positive diagnosis in cases of hæmorrhagic small-pox occurring at the beginning of an outbreak of the disease, and recited cases to illustrate this. He also spoke of another class of cases still more obscure, when the patient has a second attack of the disease.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.

THE tenth annual session of the Association was held at Indian Harbor Hotel, Greenwich, Conn., August 25, 26 and 27.

FIRST DAY.— MORNING SESSION.

The meeting was called to order by the President, DR. EDWARD WIGGLESWORTH, of Boston, who delivered the following opening address:

Gentlemen, — Just ten years ago, at Philadelphia, I had the honor of calling to order the first public meeting for the organization of this Association. Our specialty for the first time, received national acknowledgment. Our guerrilla warfare was over, and our subsequent record has been one of unbroken successive victories over bigotry, error and ignorance.

But the day of paladins is past and our ranks will admit more recruits. There are still remaining opportunities for more extended instruction of students in medical schools, while the lack of hospital facilities for the proper clinical treatment of diseases of the skin, is a standing shame and disgrace to our municipal authorities, our hospital boards and to the medical profession itself. "As now arranged nearly everywhere amongst us, these institutions refuse to a large class of sick persons the benefit of hospital residence either wholly, or offer them, if received, not we may fairly say, the best medical skill it is in their power to procure." Some progress has, however, been made. New York has now a special hospital for skin diseases, besides two wards in the Charity Hospital, and Philadelphia has special clinics with beds at three different institutions.

That the workers are ready as soon as they shall have opportunity, is evident. Ten years ago, our officially recognized representatives were, four professors, five clinical professors, one instructor, and six lecturers; total sixteen. To-day, we number seventeen professors, eleven clinical professors, six instructors, and sixteen lecturers; total fifty. Nor do I include genito-urinary surgery, which I regard as a distinct specialty from that of dermatology, which of course includes syphilis.

About twice as many cases of diseases of the skin are now annually treated by specialists as there were ten years ago.

The contributions to American Dermatological literature during the past decade, include the best treatises, hand-books and atlases, the only periodicals and some of the best monographs of the time, in the English language.

Our sole local organization, the New York Dermatological Society, is as active as ever, and the good work which it has already done is constantly increasing.

Two honorary and three active members of our original Association have passed away since its organization. Twelve active members, all living, have been added to its ranks. So much for our material progress and present prosperity.

Other objects of the foundation of our Association have been by no means neglected during the past ten years. There exists to-day, a harmony and good feeling amongst us which, but for the personal acquaintanceship resulting from the formation of this Association, never would have existed. We have come into better accord as to the "Nature and Treatment of Skin Diseases." Our increased membership proves that our Association is "held as a place of aspiration;" and it has consistently required "independent work in our department" as the essential preliminary step toward the acquisition of such membership. The systematic work of our standing committee upon statistics, has already furnished valuable data for comparison, as well as a series of excellent reports upon "Leprosy in America." Concerted official effort has done much and will do more to repress the rank luxuriance of growth of dermatological nomenclature and to furnish a "uniform and simple system."

While much has been accomplished, much still remains to be done. The idea of specialism, already

rooted, is to be nurtured and trained in the minds of the profession and of the public, and the practical development, socially, of our specialty itself is to be elaborated in many minor details. The pioneer must no longer prove a martyr. A knowledge of the weaker side of human nature, useful for selfish purposes, financial ends, must no longer be allowed to usurp the province of exact scientific acquaintance with disease, inuring to the benefit of our race. The "elaborate division of labor" is "as useful and successful in a learned profession as it is in the mechanic arts," for it is merely a relative question of height of standard. Specialism substitutes quality for quantity, which substitution is the essential characteristic of the civilized man as distinguished from the savage, while the rapidity of such substitution gauges the progress of civilization itself. Medicine is merely that complex whole which results from the combination of all its component parts, and their individual advancement is the criterion of its own progress.

Science is only exact knowledge. Medicine is that knowledge specially directed to the physical welfare of mankind, and specialism is only that further subdivision rendered necessary by the very various parts, composing the individual, and possible by the extension of our opportunities for studying these parts due to increase of mechanical means for enlargement of the field of our hitherto unaided senses. No one can to-day, "take all knowledge to be his province." Science does not culminate in a Jack-at-all-trades, least of all in one whose conscience has become anæsthetized by custom, who confounds his own limitations with the "limitations of human understanding," and his own ignorance with "the immaturity of medical therapeutics." The specialist builds his own boundary-wall and cannot, if he would, poach upon the preserves of others. He "distinguishes what he can do from what he can not," thus filling the old definition of the best physician. He cannot maltreat a patient, and when compelled to confess ignorance and seek superior wisdom, charge the wronged sufferer another and still higher fee for a "consultation," which is in reality a confession. It has been sarcastically called "the sole duty now-a-days of the family doctor to decide what specialist shall be summoned." It certainly is his duty, and a very important one as a man of honor, to decide whether any one, and if so, who can probably accomplish that wherein he admits that he himself has failed. Unfortunately, many know so little that they are even ignorant of how much is known by others; but in many respects, the specialist has already raised the average standard of requirement for general practice to such an extent, that much of the old routine practice of physicians who treated their patients for the very diseases for which they referred members of their own families to the specialist, has now become punishable mal-praxis. But the general practitioner has his revenge in opposing as unnecessary the hospital appointment, and even the private practice of the very specialist to whom he himself flees as "a very present help in time of trouble."

We are told that "the human body is made up of parts and functions so thoroughly interdependent, that it cannot be parcelled out into defined and isolated regions." It can and it cannot. What scientist divides a country into square miles and attempts to become thoroughly conversant with every atom existing in each of those miles? The special divisions of study are rather the flora, the fauna, the geological strata, etc., though all these may pervade identically every mile of the region. If regional surgery is possible, then specialties are certainly not contra-indicated. We hear of "appalling pathological conglomerates" due to lack of proper "general medical treatment." Not only "conglomerates" but often single lesions are very variously diagnosticated by different general physicians, and the "conglomerates" are usually merely the aggregated effects of original causes which might have been obviated by proper investigation in due season, on the part of suitable specialists.

The aforetime "consulting physician" meant one who in addition to his general acquirements knew more about some particular thing than any one else. We may be sure that his general acquirements had to pay the penalty. To-day, we honestly admit this and renouncing the practice obtainable by general acquirements, keep to that particular thing of which we know more than others. No one has mental ability enough at the present time to add to the greatly extended knowledge necessary to the general physician, the intensified fundamental acquaintance with detail needed by the specialist. Life is too short for the ablest intelligence to exhaust even any one specialty. The physician may, like Newton, "think the thoughts of God after him," but the thoughts of the infinite upon the smallest molecule of matter, call for more than the limits of a finite existence. The true consulting physician of to-day is the specialist and he should therefore receive this title at the hospitals with which he is connected, while those ex-physicians, called consulting but never consulted, should receive their true and proper title of emeriti.

But enough of the "idea of specialism." The public will in time appreciate the absurdity of being content with inferior results in one branch of medicine, because, forsooth, there are so many others in which their medical adviser is equally or more at home. It will reason rather that he who "insists upon doing the work of ten men, manifests a quality of mind which we can only call arrogance, and which challenges for his work severe criticism." Versatility will not atone for crude and imperfect work, any more than will lack of time, hurry of life, keenness of competition, or financial necessity and it is merely brazen self-assertion which delights "not so much in doing the thing well as in showing how well he can do it."

Believing in the ultimate achievement of all possibilities and in the progress of Truth, I have no doubt as to the future of specialism if we are honest and earnest. Not infinite omniscience, but infinite morality is the duty of the specialist, and this conscientiously carried out, will blunt the sharpest dart of the hostile general practitioner. While visions of what yet remains to be accomplished might well lead us almost to despair, a mere glance at the generally prevailing ignorance on the part of both physicians and their patients, shows conclusively that we and our work are imperatively demanded.

Dr. Wigglesworth next considered in detail the duties in the future, of members of the Association as to the establishment of special skin wards in all general hospitals; as to a revision of the existing nomenclature and classification of skin diseases; as to improvements in the Annual Reports of Transactions; the use

of the metric or international decimal system; more extended statistics; the establishment of a permanent committee upon new remedies; the question of fees and the remuneration of physicians by others of the same profession; the desirability of a (proposed) "consistent schematic plan for the report of cases," always accompanied by a summary, and the duties of specialists as to instruction. He mentioned the establishment in New York of a society for the prevention of contagious diseases. Attention was called to the proposed union of all the special medical associations of America into a general "Congress of Physicians."

Then with congratulations upon the past and hope for the future and a request for coöperation and support in the discharge of his duties, he welcomed the members present and declared the meeting open for business.

The first paper read was entitled:

ERYTHANTHEMA SYPHILITICUM,

by EDWARD BENNET BRONSON, M.D., of New York.

The purpose of the writer was to call attention to certain cutaneous eruptions of an erythematoid character occurring in connection with syphilis, and so far as possible determine their etiology. In the first place, a case was reported of a syphilitic patient who developed a peculiar eruption upon the head, hands and feet. Although the eruption presented no pronounced syphilitic characteristics, it was regarded as due to syphilis for the reasons that it was shortly followed by an outbreak of well-marked specific efflorescences on various parts of the body, and, moreover, there was a transformation of the eruption upon the head, into infiltrated lesions presenting a distinct syphilitic character; the eruption first appeared on the face in the form of an erythema which was covered with vesiculo-papular efflorescences. Later a similar outbreak occurred on the nape of the neck. The vesiculo papules broke, leaving excoriated surfaces of a diphtheroid character from which there exuded an exceedingly abundant, foul-smelling discharge. Soon after, vegetating growths made their appearance, which upon the bearded parts of the face were quite exuberant and resembled condylomata acuminata. Those upon the neck, formed more discrete, tuberous prominences and had the appearance of condylomata lata; while upon the upper parts of the face, the elevations were nummular and had comparatively smooth though somewhat lobulated surfaces. After a week or two, the erythematous areas, which formed the bases of the vegetating lesions, became the seats of a gradually increasing, copper-colored infiltration. The palms and corresponding surfaces of the fingers, were covered with a deep red, sharply circumscribed erythema, which was followed by lamellar desquamation. A similar eruption occurred in patches upon the soles. The finger-nails were all more or less affected with onychia sicca. Upon the body and limbs, several crops of well-marked syphilitic papules succeeded each other and finally all the manifestations yielded rapidly to mercurial treatment. The preliminary eruption in this case was characterized as an erythanthema dependent in some way upon the specific disease. Other instances of erythematoid eruptions occurring incidentally to syphilis, were referred to as being more or less analagous to the above cited case.

Allusion was made to the syphilitic roseola as a possible case in point; then to the preliminary erythematous eruptions observed in hereditary syphilis—the *érythème précurseur* of the French — and also to certain forms of coincident or preliminary erythema as described by Hebra, Neuman, Danielesen, Dipp and Finger. Attention was next called to the syphilitic erythema nodosum of Mauriac and three cases of this affection were reported, in one of which, the erythematous eruption was apparently succeeded by a syphilitic infiltration that pursued a course similar to that of a breaking-down gumma of the skin.

Finally it was attempted to define more precisely the etiological relations of these various erythematoid eruptions occurring in connection with and probably as a consequence of syphilis. It was maintained that probably they were not equivalent in their mode of origin to the syphilodermata, but rather to certain angioneurotic or neuritic affections, which they closely resembled. The true syphilodermata are always characterized by a specific infiltration and are probably the result of a determination of the materies morbi to the surface. They are therefore pathognomonic of syphilis. The erythanthema syphiliticum, on the other hand, is only an indirect effect of the syphilis, the result of reflex irritation of the skin from the action of the disease upon nervous centres, and therefore not pathognomonic of syphilis. The fact that this might be followed by a true syphilitic infiltration *in situ*, was regarded as analagous to the effect sometimes observed of traumatic irritation in syphilitic subjects, where local injuries became the seat of specific infiltrations.

DISCUSSION.

DR. I. E. ATKINSON, of Baltimore. I wish to say a few words in regard to pathognomonic syphilitic eruptions. In this connection, a great deal of caution must be exercised, and I think we should not dogmatize with regard to the specific lesions of syphilis. Lesions similar to those described by Dr. Bronson are not of excessive rarity in cachectic subjects and in cases of malignant syphilis, but in my experience they have always been manifestations of late or tertiary syphilis.

DR. J. C. WHITE, of Boston. The occurrence of the forms of disease which have been described are so rare in syphilis, we know so little of the nature of erythema nodosum and its causes, and we know so little of the nature and causes of so-called erythema herpetiformis, which, I think, should be called erythema multiformis, that it seems to me we must have some more exact data before we can regard these affections as a necessary sequel of syphilis, and as anything more than accidental occurrences. While there is nothing *a priori* against a causal relation existing between these conditions and syphilis, such relation has not been proven. The early roseolous exanthematous condition of the skin in syphilis is of sufficiently frequent occurrence to be looked upon as a distinct feature of syphilis. This is wholly unlike the rare forms of dermatitis which have been described to-day.

DR. F. B. GREENOUGH, of Boston. Syphilitic roseola seems to me to be decidedly distinct from other forms of congestion of the skin, especially in one point, that is, during the subsidence of the congestion, little points of distinct congestion continue for a long time. These appear to represent the follicles. The points of pigmentation are also an almost constant occurrence. This I have not seen in other forms of affection of the skin.

Dr. G. H. Tilden, of Boston. It seems to me that in the present state of our knowledge, it would be more philosophical to consider the appearances described as accidental, rather than as dependent upon the specific disease.

RUBELLA OR RÖTHELN,

by Dr. I. E. Atkinson, of Baltimore.

The paper was based upon a review of the literature of the subject, and a study of the reported cases. The disease was regarded as distinct from measles and scarlet fever. The period of incubation varies between two and three weeks. In many cases there is no prodromal stage. There may, however, be prodromata for twelve or twenty-four hours. Catarrhal symptoms are generally absent, but they may be present. Sometimes there is congestion of the throat. Swelling of the lymphatic glands is a peculiar and marked symptom. This swelling is painful, but does not pass on to suppuration. In many cases fever is absent. The eruption first appears on the forehead and face, and in the course of a few hours, spreads to other parts of the body. The eruption is more or less irregular, being more intense in some situations than in others. From the beginning to the disappearance of the eruption is usually three or four days. In the greater number of cases, desquamation fails to occur. Complications and sequelæ are not unknown, the most common being bronchitis, pneumonia, and gastro-intestinal disorders. Renal affections may follow this disease. Relapses occasionally occur, but not later than the end of the second week. The prognosis is almost always favorable.

The only difficulty in diagnosis is in connection with measles, and in isolated cases, a thorough consideration of all the points is essential to a correct conclusion. Very little treatment is required, except in the presence of complications.

On account of the confusion existing as to the nomenclature of this disease, the speaker suggested that rubella be accepted as its proper title, and that it might be known in popular language as epidemic roseola.

DISCUSSION.

The President. Several years ago I suggested that measles be called morbilli, and rubella or rötheln be used to signify what is termed German measles, and roseola be reserved as the title for the rose-colored spots seen in syphilis and other conditions. There does not seem to be any necessity for the introduction of a new term.

REPORT OF A CASE OF LYMPHADENOMA (MYCOSIS FONGOÏDE) AND AUTOPSY,

by Dr. G. H. Fox, of New York.

(In the absence of the author, the paper was read by the Secretary).

The paper described the case of Mrs. G., aged thirty-three years, the mother of six children. During pregnancy, in the summer of 1881, she suffered with general pruritus, which passed away after her confinement in October. A year later, small, flattened, circular tumors appeared in the axillæ and on the breast. These became moist, and were accompanied with a burning sensation. The eruptions disappeared from these situations, and reappeared upon the back and other portions of the body. After the birth of her last child in February, 1885, a tumor developed at the inferior angle of the left scapula. The lesions on the other parts of the body disappeared, with the exception of two spots on the finger and one on the left cheek. The tumor on the left scapula gradually softened and disappeared.

The patient was admitted to the hospital in October, 1885, and was fairly well nourished. There were, at this time, numerous tumors over the body, some of which were superficially ulcerated. The worst tumors were on the breast. Hypodermic injections of Fowler's solution were used without benefit. Chaulamooga oil was given in increasing doses until forty drops, four times daily, were taken without causing any improvement.

The patient died in April, 1886. The microscopical examination gave the usual appearances of these growths. The internal organs were found to be normal.

DISCUSSION.

Dr. G. H. Tilden, of Boston. One year ago I reported a case of this disease. I said then that it was not sarcomatous. Rindfleisch states that he has found a distinct micrococcus inside of the bloodvessels in this connection, and recently this has been confirmed by another observer. It looks as though what we ordinarily know as malignant lymphoma, affecting the lymphatic glands, with deposits in other parts of the body (Hodgkin's disease), is one of the infectious diseases. I should not be surprised to find that this *mycosis fongoïde* is a variety of the same disease, and that it is nothing but an acute infectious disease.

The next paper, entitled

A NOTE RELATIVE TO THE BULLOUS ERUPTION OCCURRING AFTER THE INGESTION OF IODINE COMPOUNDS,

by Dr. J. N. Hyde, of Chicago, was (in the absence of the author, read by the Secretary).

The first case described was that of an infant seven months of age. Six weeks before coming under observation, the child had suffered from a febrile attack, the exact nature of which was not known. Three weeks later the eruption made its appearance. The lesions at first presented the appearance of chicken-pox. The child's face, the dorsal aspect of the hands and forearms, and the scalp were covered with isolated whitish, split-pea, to marble-sized, flattened, slightly umbilicated lesions, resembling molluscous tumors. The contents of the lesions were inspissated, thick, and grumous, and of such consistency that they did not escape on rupture of the sac. It was learned that iodide of potassium in one-grain doses had been administered for the febrile attack. On the discontinuance of the iodide and the use of antiseptic powder, the lesions rapidly disappeared.

Case II. A lad, fifteen years of age, who had recently undergone an operation for necrosis of the right femur, developed an eruption involving the entire body. There were two distinct sets of lesions. That which predominated was composed of annular, circinate plaques, varying in diameter from several centimetres to half a meter. There were also here and there, particularly about the finger ends, distinct blebs. The patient had been taking iodide of potassium in fifteen-grain doses. This was discontinued, and the eruption speedily disappeared.

There are two distinct types, the bullous, and the quasi-bullous eruption produced by the ingestion of iodide of potassium. In the first form, the patients

are often well advanced in years, often cachectic, and frequently affected with syphilis or other grave disease. In what may be regarded as a second sub-form of this exanthema, there are di- or poly-morphic symptoms. Here bullæ are commingled with papules, tubercles, and other patches of disease. The speaker then described other cases of similar eruptions recorded by various writers, and, in conclusion, presented the following interrogative propositions:

(1) Are there not three sub-forms of the bullous exanthema developed in certain individuals after the ingestion of iodide of potassium?

(2) Is not the first and most common of these to be generally recognized in persons of advanced age and cachectic condition, the rash being then present in the form of typical bullæ?

(3) Is there a second and still rarer sub-form, in which the eruption is displayed in di- or poly-morphic manifestations, typical, perfect bullæ being then mingled with papules, tubercles, scarlatiniform maculations or with other and different lesions?

(4) Is there not a third and rarer sub-form, the quasi-bullous rash to be most frequently recognized on the face and dorsal aspect of the hands and forearms of infants and children, where the lesions are semi-solid, slightly umbilicated and filled with inspissated yellowish matter and which may shrivel and dessicate on the suspension of the drug inducing the condition?

(5) Is this last described lesion one to be recognized solely as the result of the ingestion of iodide of potassium, never under other circumstances, and one as peculiar to the special condition it represents as is the gumma to syphilis?

DISCUSSION.

DR. R. W. TAYLOR, of New York. While the most general eruption produced by iodide of potassium is an acneiform exanthem, yet it may cause dermatitis with multiform lesions with bullæ, which may contain serum, pus or even blood. I think that some of the cases of extreme dermatitis multiformis which have been described, have been due to this cause.

I recently saw a peculiar form of iodine intoxication. It was in a case of gummatous infiltration of the pharynx where iodoform had been resorted to as a local application. In the course of two hours it produced a diffuse eruption on the face, neck and hands. On the hands it assumed an eczematous character.

DR. J. E. GRAHAM, of Toronto. I have had one case similar to that described by Dr. Hyde. A young man twenty-two years of age, had contracted syphilis two years previously. Noticing some pimples on his face, he secured a preparation of iodide of potassium containing five grains to the dose. I saw him two days after he had begun to use this preparation. He then had a bullous eruption principally upon the face and neck. At that time I thought that it was a tertiary manifestation and increased the dose of iodide to fifteen grains. Two days later, the eruption on the face was much increased and recognizing the cause of the condition, the drug was stopped and the eruption rapidly disappeared.

DR. I. E. ATKINSON, of Baltimore. One year ago, I saw a case of what was supposed to be malignant syphilis; the patient had had syphilis and had been put on the use of iodide of potassium. The lesions continued to increase and after the iodide had been taken for six months, I saw the case. There was an enormous formation of scar-tissue over the face and neck. In addition there were bullæ and elevated infiltrated plaques. The appearances presented were unlike those produced by syphilis and I thought that they were due to the iodide of potassium. The drug was stopped and in six weeks the ulcerations had healed, the cicatricial tissue of course remained. I think that we can not lay too much stress upon the dangerous conditions which may follow the administration of the iodides.

EVENING SESSION.

The first paper was on

PRECOCIOUS GUMMATA,

by DR. R. W. TAYLOR, of New York.

After a thorough consideration of the subject and the presentation of a number of illustrative cases, the following conclusions were presented.

(1) Like the osseous affections, affections of the nervous system, malignant syphilides in general besides many other affections, the gummata syphilis may be precocious in appearance, occurring as early even as the second month of infection but usually in the third or fourth month or after that time.

(2) Of the precocious gummatous syphilide or gummata, there are three quite clearly marked forms, first, the early, general and copious form; second, the more localized form which may invade several regions, is usually symmetrically distributed and sometimes even is confined to one region, particularly one side of the face or scalp and the roof of the mouth; and third, a form in which more or less severe neuralgias precede and accompany the eruption, which in many particulars resembled simple erythema nodosum, but which in its etiology is not in any way related to this simple form of eruption but is a direct outcome of the syphilitic diathesis.

(3) That these precocious gummata partake in general of the features of those of later forms, but that they differ in the more acute invasion, in a much more rapid course and are usually not as profound and destructive in their action as the classical eruption.

(4) That of these precocious forms of gummata, there are found to be two varieties, one a non-ulcerative or resolutive, the other, ulcerative.

(5) That in the treatment of these precocious syphilides, a combination of mercury and iodide of potassium is much more efficacious than is mercury alone.

(To be continued.)

— The treasurer of the Dundee Royal Infirmary recently received a donation of £100 from a grateful patient, in return for treatment received by the latter while he was an inmate of the Old Infirmary in the year 1843.

— The Paris Academy of Medicine is reported to have announced the following remarkable subject for a prize essay: "Préciser par une série d'observations s'il existe un traitement abortif de la syphilis confirmée." To abort a confirmed syphilis appears to be as encouraging a task as the proverbial locking of the stable door after the steed is stolen.

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 9, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

THE ADDRESS OF MR. ERICHSEN AT THE BRITISH MEDICAL ASSOCIATION.

THE addresses at the British Medical Association of the present year were of more than usual interest, and the address of Dr. Billings published in the JOURNAL appeared in quite remarkable company. Among these addresses, that of Mr. Erichsen attracts attention for the high scientific plane to which it would raise surgery, and especially for the assumption that perfection has been already reached in the mechanical details of the art, and further progress in that particular rendered impossible. Further progress, according to Mr. Erichsen, will be in the science of surgery, rather than in the art. The following quotation will serve to illustrate Mr. Erichsen's idea.

"That the final limits of surgery have been reached in the direction of all that is manipulative and mechanical there can, I venture to think, be little doubt. Within these limits there may be much of movement, of change, of modification in the technique, if I may borrow that word from art; but movement is not necessarily advance; it is often the mere restlessness engendered by dissatisfaction with established methods; change may be the outcome of mere personal vanity, or of more unworthy motives."

What Mr. Erichsen has said regarding the necessity for advancement in the science of surgery we all accept, but it is very difficult to accept the assertion that progress in mechanical detail is at an end. The very great changes — changes which are distinct improvements and advances — within the last few years, none of which could have been foretold, are, to minds differently constituted from Mr. Erichsen's, indications of still further changes in the future.

The very instances of practical perfection which the talented author adduced may be counterbalanced by others where perfection is evidently far off. If ovariotomy has reached a high point of excellence, there is still uncertainty and doubt as to the proper method of treatment of surgical diseases and injuries of the intestinal tract. If the operation for strangulated hernia gives results which leave little to be desired, who believes that mechanical perfection has been reached in the operation for the radical cure of hernia? And one might continue the list of imperfections to great length.

It does not require a very vivid imagination to conceive great changes in operative details from more perfect instruments. To give a single instance, it is not beyond possibility that we shall some day see the still modern rapid lithotrity materially modified by an instrument which, having once seized a stone in the bladder, shall never release it until it is completely pulverized and evacuated.

In his recent address on the "Study of Science," Sir John Lubbock quotes the title of an essay of Boyle's, "Of man's great ignorance of the uses of natural things; or that there is no one thing in Nature whereof the uses to human life are yet thoroughly understood," and he considers the saying as true now as when it was written; and among the uses to human life may certainly be included the surgical applications.

Modern inventions are not yet in such a state as to yield their best results to surgery, and that marvellous discoveries still await the explorers of nature, no one can doubt. Not until man has perfect knowledge of and perfect control over the forces of nature can we be sure that the limit of their application to surgery has been reached. What changes the electric light, for instance, may finally produce in the art of surgery it is difficult to foresee exactly, but he must be a conservative of conservatives who denies the possibility of bringing about changes, even radical changes, in surgical manipulations by the illumination of internal organs by this means.

Even the advances in the science of surgery to which Mr. Erichsen looks forward must necessarily bring changes and improvements in the art. The practical application of scientific discoveries cannot be understood beforehand nor bounds set to the extent of their influence. Who could possibly have known of the influence Pasteur's researches on spontaneous generation would have on surgical theory and art. How can any man foresee the influence upon surgery of our very recent knowledge of the ptomaines and leucomaines. Instead of saying with Mr. Erichsen "The old lines of ordinary clinical observations and dead-house pathology have long since been followed to their final termination," we should prefer to say, the experimental researches of the biological, physiological and pathological laboratory must guide, illustrate, and illumine the ordinary bedside, and dead-house observations to be in turn directed and confirmed, the two methods of research acting together to build up a yet nobler art on a wider and more scientific basis.

Mr. Emerson has taught us that "if anything could stand still, it would be crushed by the torrent it resisted," and it causes quite a shock to learn Mr. Erichsen's opinion that surgical art is already at a standstill. At first one feels indignant that so eminent a man should thus set bounds to the art of which

he has been for so many years a master. A more careful reading serves to show that Mr. Erichsen desired to emphasize the fact that the science of surgery needs particularly to be studied and that it is in the line of science that advance must be made; apparently in his desire to emphasize this, he has too emphatically spoken in regard to the present position of the art. It is a question, after all, if there is any real difference of opinion between Mr. Erichsen and ourselves. Much of what we should regard as advance, Mr. Erichsen would perhaps call change in technique, and the art and science are so mutually dependent that it might not always be possible to say to which division the advance should be ascribed.

In one thing Mr. Erichsen would agree with us undoubtedly. If he considers that the art is perfect he will also admit that not every practitioner of the art is perfect. No man can rest secure in the thought that he has himself reached the standard of perfection. We feel sure that no careful searcher will find difficulty in imperfections in the art itself.

STATE INSPECTION OF MILK.

THE second annual report of the New York State Dairy Commissioner, lately issued, furnishes a rather remarkable instance of how a large amount of money may be expended with comparatively meagre results. It does not appear from the report what the exact appropriation may be, but that it is large may be inferred from the fact that, not including the salary of the commissioner, the expenditures for the first nine months of the year amounted to more than thirty thousand dollars. For such a sum as this the people of New York State have a right to expect much more in the way of inspection of dairy products than is shown by this report, which, it may be remarked, contains considerable irrelevant matter, much that is both useless and absurd, and not a little taken bodily and without credit from German works.

In the inspection of butter, eight collectors and several chemists and lawyers were employed. More than eight thousand samples were purchased, but only two hundred and twenty-eight, or one in thirty-five were delivered to the chemist for analysis. Of the cases taken before the courts but fifty-four were disposed of, resulting in thirty-one convictions and twenty-three acquittals. It is but just, however, to note that the commissioner and his co-workers have been and are very much hampered by tiresome delays due to the complex judicial system.

In the department of milk inspection nine collectors were employed on an average of one hundred and ten days each. Over nineteen thousand specimens were "examined" but only three hundred and forty-one, or one in fifty-seven, were submitted for analysis. The local authority at Buffalo had nearly as many analyses made from that city alone. It does not appear from the report that more than six convictions for violation of the milk law had up to the end of the year been obtained.

This is not what might be called a very brilliant showing and is in marked contrast to the same work as carried on by the Massachusetts Board of Health, or by the Inspector of Milk for the city of Boston. The general supervision of the milk and other food supply of that State is under the direction of the Board of Health, which employs two collectors and several chemists for the work. The collectors not only obtain samples from all parts of the State but do all the work involved in the preparation of cases for court, and act as prosecuting officers; they are not engaged in making a record of samples purchased but not delivered for analysis, nor of miles travelled, as is apparently the custom in New York, where three of the collectors employed on an average of two hundred and sixty days, travelled seventy-three thousand miles, "examined" more than fifteen thousand specimens, and delivered two hundred and seventy-four to the chemists for analysis. In Massachusetts the collectors deliver all their samples to the several chemists who report directly to the Secretary of the Board of Health, and the latter sends warnings or gives orders for prosecution according to circumstances. So far as the inspection of milk and other dairy foods is concerned that State Board of Health, with a very small appropriation and with a limited number of employees, performs more actual work and shows much more tangible results than the New York Commissioner with his large appropriation and staff of collectors, chemists, lawyers, and assistant commissioners.

The New York authorities, however, are doing a very important work which it is hoped other Boards may at no distant date have authority to undertake; that is, the inspection of dairies, creameries, stables and cows. The importance of thorough work in this direction cannot, in the light of recent observations and investigations on the communicability of diseases, be overestimated.

It may be remembered that it was proposed before a legislative committee in Massachusetts in the early spring to take the work of inspection of milk and milk products and the enforcement of the law from the jurisdiction of the Board of Health, and delegate it to a commissioner, as in New York. The work of the latter was held up as a model of excellence by those who were interested in the movement, who were two in number, one a large dealer, the other a candidate for the office of commissioner. The proposition died an easy death and in view of the manifest undesirability of the change it is probable that no more serious attempt will be made.

MEDICAL NOTES.

— In the last five years Billroth has performed operations on the stomach in thirty-two cases, with nineteen fatal results. Out of fifteen gastrectomies for cancer, there were seven recoveries.

— Dr. H. A. Kelley, of Philadelphia, reports the successful removal of an ovarian tumor weighing one hundred pounds. Dr. Goodell removed a tumor of one hundred and twelve pounds from a woman who weighed after the operation but seventy-four pounds. In each case the tumor reached the patient's knees, and she could not lie down.

— A tendency to an increase, in the proportion of female children born has recently been noticed in Paris. Normally, the male children outnumber the female in the proportion of 103.5 boys to 100 girls, but for the last few months the proportion of girls born has undergone a remarkable increase. Taking twenty-three weeks, the average has been exceeded in eleven. The same tendency appears to exist all over France, and is inspiring serious apprehension to fathers of families who will be called upon to supply an extra number of *dots*.

— In the *Lancet*, June, 1886, p. 1148, Mr. B. F. Hartzhorne writes that he has used cocaine with beneficial results in parturition. The manner in which it is used is as follows: By means of an ordinary glass syringe, a compound, composed of six parts of cocaine, twenty-four of vaseline, and twenty of glycerine, is injected as high up the vagina as possible. By this means the cocaine is applied to all parts of the vagina, insuring a more lasting effect than when applied in solution. The pain due to pressure, the dilatation of the cervix, and the expansion of the perineum, is so markedly relieved by this means, according to the writer, that an ordinary labor is deprived of half its agony.

— Medical literature contains many records, remarks the *Medical Press and Circular*, of the curious symptoms produced by one or other variety of the parasites which infest some part of the alimentary canal. It is, however, not often that death can be distinctly traced to them, and the details of such a case just recorded on behalf of the police in Paris are sufficiently extraordinary to call for more than a passing remark. A young girl in good health was found dead in bed by her parents. Nothing could account for her sudden decease, and in their fear of the possible consequences of this unexpected death, they resolved to leave the body in some sequestered spot to be found or buried without any explanations being asked. When the body was found, its discovery created the greatest excitement; thousands of people visited the *morgue* daily to obtain a glimpse of the poor little corpse, no doubt being entertained as to the fact of a wanton crime having been committed. It now appears that death was due, not to violence nor poison, but to the somewhat prosaic accident of impaction of a bundle of intestinal worms in the larynx during sleep. The occurrence is certainly a curious one, and shows what unexpected causes may be at work in leading to a fatal result. The extraneous elements of interest in the case were entirely due to the foolish action of the parents, whose conduct was certainly reprehensible to the last degree.

Miscellany.

A CONTRAINDICATION OF PARALDEHYDE.

It has been asserted that paraldehyde does not give rise to any unfavorable secondary symptoms, and that there is no known contraindication to its administration, remarks the *Therapeutic Gazette*. It quotes, however, from the *Neurologisches Centralblatt*, No. 11, 1886, a little note by Dr. Sommer, of Allenberg, which renders the correctness of these views doubtful. A patient, eighteen years of age, who, for six successive days, had taken daily doses of one drachm of paraldehyde, showed on the seventh day, a few minutes after having drunk half a bottle of beer, a deep scarlet injection of the skin, covering almost the entire head, neck, back, posterior surfaces of the lower extremities, and partially the chest, abdomen, and upper extremities. This peculiar phenomenon lasted half an hour. For the sake of an experiment, Sommer gave the patient on the next evening another dose of paraldehyde, followed by a small quantity of alcohol on the next morning. The same vascular injection having appeared again, Sommer concluded that paraldehyde ought not to be given to patients presenting atheromatous defects, and should, at least, not be employed in connection with alcoholic liquids. Only one other observer, Eickholdt, has previously observed similar interferences of the circulation following after the employment of paraldehyde. He noted the occurrence of cerebral congestions and of vaso-paralytic symptoms after the prolonged use of this drug.

THE DANGER OF SYNCOPE IN HOT BATHS.

It is surprising, says the *Lancet* (July 3), that deaths by syncope during the use of hot baths are not more common than the coroner's court returns would show them to be. The peril of faintness by the mere determination of blood to the surface of the body, thus quickly depriving the heart of its usual normal support and stimulus, is very great. In cases of muscular weakness of the heart this danger must be imminent whenever the "hot" or even the "warm" bath is used. Apart from this obvious risk, however, there is always the possibility that in weakly or too impressionable states of the nervous system the peripheral stimulation produced by the application of heat to the whole of the cutaneous extremities of the afferent nerves may so act on the centres as to arrest the evolution of energy by an inhibitory influence. It is doubtful whether we lay enough stress on this consideration when prescribing the use of such external agents as act on large areas of surface and strongly impress the nerves there commencing. We know how burns of even moderate severity may kill by the impression they produce on the centres of vitality from the periphery. There is much to learn in regard to the nature and extent of the central effects which may be thus caused. Whether for good or evil, the application of heat or cold to the whole surface is a potent measure, and one that ought not to be recklessly resorted to, more especially in cases of great susceptibility, involving such excitability of the nervous centres as often co-exists with fairly good health in a weakly body.

CHINESE MEDICINE.

A CORRESPONDENT of the *Columbus Medical Journal*, in an interesting letter regarding medical practice in China, says:

"When a child is born, the umbilical cord is measured to the top of the child's head, cut from the placenta at that place, and when this mass of decaying cord loosens from the child, it is sold to the druggist. Cat's heads and many other disgusting things are purchased by the same functionary. The body of a still-born child, provided said child is a first-born and a son, is supposed to contain medicinal properties.

"With such a pharmacopeia, what can we expect in the profession? We find exactly this: A set of ignorant, superstitious men, who do great harm, and if they do any good it is purely accidental.

"I give below the translation of a prescription, which was written by a native doctor for a man who had applied to him with chronic dysentery:

℞ Powdered gentian,
" catnip leaves,
" root of taraxicum,
" root of white ginger,
" smilax,
" black pepper,
" root of persimmon tree,
Of each quantity sufficient to half-fill a wine-glass.
Powdered rhubarb,
" digitalis,
Calomel.
Of each as much as can be held between the thumb and forefinger.
Three inches of umbilical cord, powdered.
One snake skin, powdered.
One cat's head, fresh if possible.
Sig. Boil all these in five quarts of water for three hours; cover the patient with many quilts, and cause him to drink all the medicine within thirty-six hours, as hot as it can be swallowed.

"I have found prescriptions very near like this one in the hands of patients suffering from leprosy, pneumonia, phthisis, small-pox, paralysis, typhoid fever, etc., proving, as I believe, that their treatment is entirely haphazard.

"Gynæcology and obstetrics are not practised at all by the doctors, the seclusion in which the women live in that land rendering it impossible.

"Surgery is practised in the same barbarous and ignorant manner which we have noticed in their general therapeutics. I will give one instance which fell under my observation. I saw a surgeon drive three steel spikes, about a finger in length, into a rheumatic knee. Of course the result was an anchylosed joint. The patient endured the operation with great fortitude, having no anæsthetic."

THE INFLUENCE OF DRUGS ON NURSLINGS WHEN ADMINISTERED TO THEIR NURSES.

FEHLING has recently, we learn from the Paris correspondent of the *British Medical Journal*, studied experimentally the effects on nurslings of certain drugs given to the women who suckled them. When doses varying from two to three grammes of salicylate of soda were administered to the nurse, every time that a child was suckled within an hour after the administration of the dose the salicylate appeared in its urine.

After an interval of twenty-four hours there remained no trace of the drug. When the child was suckled very soon after the medicine had been taken, the salicylate could not be found in its urine. Elimination was completed at the same time in the mother and the child. With iodide of potassium the results were the same. The milk, when analyzed, gave the characteristic reaction. In the infant, elimination lasted seventy-two hours, in the mother forty-four. After twenty-four hours, the milk still contained iodide of potassium. With ferrocyanide of potassium, reaction was very pronounced in the maternal urine, but absent in the child's. Prolonged applications of iodoform upon vaginal and vulvar wounds of women in parturition, after prolonged use, generally resulted in iodine being found in the milk and urine of the mother, but not always in the urine of the infant. The child was never indisposed, even when iodoform was used to dry up the umbilical cord. There was only a small quantity of mercury transmitted through the milk of a nursing mother, and its presence was not constant. It appeared that the food of wet nurses — even acid fruit-juices and vinegar — had no influence on their nurslings. Thornhill had stated that he observed prolonged sleep occur to children after administering to their wet nurse such narcotics as tincture of opium in doses of from twenty to twenty-five drops. Fehling observed neither prolonged sleep nor constipation in the children. Hydrochlorate of morphine or chloral, in tolerably strong doses, did not affect the suckling.

Subcutaneous injections of moderately strong solutions of sulphate of atropine produced very pronounced symptoms in the mother, and dilatation of the pupil in the infant, which disappeared in twenty-four hours. This substance should, therefore, be employed in very feeble doses. In a very great majority of cases, the milk of a woman attacked with fever had no influence upon the nursling. In those rare cases, when the temperature reaches 104°, the variations in the child's temperature were identical with those of the mother. In some instances, children had died of intestinal catarrh, where the mother's milk could be the only cause of the affection. Bumm has observed, in a case of inflamed breast, the passage of the micrococcus from the milk into the digestive apparatus of the child.

ABOUT GLYCOGENESIS.

REPLY TO DR. LIEBMANN.

THE courteous correspondent who writes from Augsburg, Germany, to last week's JOURNAL (page 219), seems strangely to have misunderstood the article on page 66 of the present volume, to portions of which he takes exception. The veriest tyro in physiology knows the conversion of starch into glucose in the alimentary canal. There is no doubt as to the absorption of glucose as such, but what is its immediate destination? It cannot all be utilized as fast as produced, nor is any excess immediately excreted as glucose by the kidneys, at least in normal states of the economy. A part, it is true, disappears in the intestinal canal by reason of its transformation into lactic and butyric acids (Lehmann) and a part may, under some circumstances, escape as sugar in the fæces; an inconsiderable amount may be absorbed by the lacteals, and with the lymph and chyle, enter the general venous circulation; the far greater part ingested, however, is taken up by the radicals of the portal vein, and is subjected to the action of the liver.

What prevents undue saccharification of the blood? What, when a highly amylaceous diet is used, keeps the due proportion of 1 to 2 per 1,000 of sugar in the circulating fluid, saves the system from being flooded by carbo-hydrates and the kidneys from all the evils attendant on persistent glycosuria?

Here we see the importance of the function exercised by the liver. Although an excess of sugar may enter the portal circulation, the liver, that watchful janitor and steward, will not (under normal conditions) allow any excess to enter the general circulation. In other words, it arrests the further march of the glucose of the portal circulation by storing up in its cells the saccharine material in some

colloidal form, which, without reconversion into glucose, is incapable of further diffusion. To this colloidal substance whose presence in the hepatic cells is capable of demonstration, Claude Bernard gave the name of *glycogen*, Charles Rouget of *zoamyline*. It is by virtue of this "sugar-detaining and sugar-assimilating function" (to quote Pavy's words) that the blood of herbivora contains no more sugar than the blood of carnivora.

Hence, as to the fact of the fixation by the liver of amyloid material (glycogen), which, under some (if not under *normal*) circumstances, is easily reconvertible into glucose, all authorities are at the present day agreed. So far, Claude Bernard's great discovery stands unquestioned. As for the manner of final disposal by the organism of this liver-starch, there is a difference of opinion. The older view — that of Claude Bernard — was stated in the article in the JOURNAL before referred to (see page 66). This view is supported (as there stated) by the argument from analogy. In brief, the liver is a reserve depot of saccharine material, which it yields up to the circulation as the wants of the organism require. All the sugar utilized by the economy must first have undergone the action of the liver, which constantly maintains that minimum amount of sugar in the blood which characterizes health. Despite the objections which may be alleged to the Bernardian theory as here stated, the probabilities seem to us in its favor, and (to quote the cautious words of Foster, in his "Physiology,") "it is not as yet disproved." Even Pavy, who has done more than any other experimental physiologist to weaken the glycæmic doctrine, as propounded by Bernard, owns the absurdity of the view that the liver can go on a whole lifetime assimilating glucose without continually restoring it to the organism, and admits that in some form unknown to him, the zoamyline is constantly given back to the tissues to be utilized for force-production and histogenesis.[1] — [ED.]

Deaths reported 1,508: under five years of age 665: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 434, consumption 202, lung diseases 78, diarrhœal diseases 291, diphtheria and croup 54, typhoid fever 42, whooping-cough 22, malarial fever eight, cerebro-spinal meningitis seven, measles five, erysipelas three, scarlet fever two. From whooping-cough, New York nine, Philadelphia six, Providence three, Nashville, Lowell, Taunton and Brockton one each. From malarial fevers, New York seven, Philadelphia one. From cerebro-spinal meningitis, New York and Fall River two each, Philadelphia, Nashville, and Lynn one each. From measles, New York four, Boston one. From erysipelas, New York two, Providence one. From scarlet fever, New York and Providence one each.

In the 14 cities and greater towns of Massachusetts, with a population of 784,210 (population of the State 1,941,465), the total death-rate for the week was 22.88 against 24.21 and 24.56 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending August 14th the death-rate was 18.9. Deaths reported 3,300: infants under one year of age 1,218: acute diseases of the respiratory organs (London) 150, diarrhœa 531, measles 54, fever 44, whooping-cough 33, scarlet fever 30, diphtheria 26.

The death-rates ranged from 12.5 in Derby to 26.9 in Cardiff; Birkenhead 24.1; Birmingham 17.4; Hull 13.8; Leeds 18.5; Leicester 20.9; Liverpool 23.4; London 18.9; Manchester 18.1; Nottingham 15.8; Sheffield 17.6.

In Edinburgh 17.2; Glasgow 19.1; Dublin 20.8.

For the week ending August 14th, in the Swiss towns, there were 26 deaths from consumption, diarrhœal diseases 16, lung diseases 10, typhoid fever five, puerperal fever, diphtheria and croup each two.

The death-rates were: at Zurich 11.5; Geneva 13.1; Basle 15.5; Berne 17.1.

The meteorological record for week ending August 28, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, Aug. 28, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 28, 1886, TO SEPTEMBER 3, 1886.

CRAMPTON, L. W., captain and assistant surgeon. Relieved from further duty at Bellevue Rifle Range, and granted leave of absence for one month to take effect before rejoining his proper station, Fort Bridger, Wyo. S. O. 108, Department of the Platte, August 28, 1886.

WOOD, L., first lieutenant and assistant surgeon. (Recently appointed.) Ordered to report by letter to the commanding general, Department of Arizona, for assignment to duty. S. O. 202, A. G. O., August 31, 1886.

SOCIETY NOTICES.

AMERICAN PUBLIC HEALTH ASSOCIATION. Fourteenth Annual Meeting. 1886. — The American Public Health Association will convene at Toronto, Canada, Tuesday, October 5, at 10 o'clock, A.M., and continue in session four days. The meetings will be held in Shaftesbury Hall, on Queen Street, West. The Executive Committee have selected the following topics for consideration at said meeting: I. The Disposal of the Refuse Matters of Cities and Towns. II. The Condition of Stored Water-Supplies, and their Relation to the Public Health. III. The best Methods and the Apparatus necessary for the Teaching of Hygiene in the Public Schools, as well as the Means for securing Uniformity in such Instruction. IV. Recent Sanitary Experiences in connection with the Exclusion and Suppression of Epidemic Disease. V. The Sanitary Conditions and Necessities of School-Houses and School-Life. (Lomb Prize Essays.) VI. The Preventable Causes of Disease, Injury, and Death in American Manufactories and Workshops, and the best Means and Appliances for preventing and avoiding them. (Lomb Prize Essays.) VII. Plans for Dwelling-Houses. (Lomb Prize Plans.) Upon the above topics a good number of able papers have already been prepared by well-known sanitary writers. Authors from several sections of the United States, Canada, and England have signified their intention of being present with papers. In addition to papers upon the selected topics, several upon miscellaneous sanitary subjects will be presented for the approval of the Executive Committee, and, if accepted, will be assigned a place on the programme. All persons who propose to present papers must be governed by the by-laws of the Executive Committee.

Concord, N. H. IRVING A. WATSON, *Secretary*.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — SECTION FOR CLINICAL MEDICINE PATHOLOGY AND HYGIENE. Boston, September 4, 1886. — The Section for Clinical Medicine, Pathology and Hygiene will meet on October 13th, and on the second Wednesday of each month thereafter during the season. These meetings have been largely attended during the last five years, and a considerable amount of good work in the departments to which they are devoted has been accomplished. There is a greater interest in questions of hygiene and public hygiene than has been evinced for a long time, and the discussions on the subjects relating to this branch have embraced the purity of water-supply, the sanitary conditions of our homes, the relations of military drill to our school system, as well as several other topics relating to the public health. The condition of medicine may at present be considered to be improving in our city, as there is a wider interest in subjects not only of purely clinical nature, but of the character of general sanitation. The younger men of the profession are more active in our Society meetings than ever before, and this in itself is an indication of great weight in estimating the status of medical science in our city. A noteworthy feature of the last year was the reading of a very interesting and able paper in the Section by one of the ladies of the Suffolk District Medical Society. The Clinical Section has been honored on several occasions by the presence of distinguished gentlemen from other cities, frequently representing special departments in university teaching: who have added greatly to the value of our meetings, and to whom the Section owes much of interest in its discussions. The discussions in the Section have been fully reported in the medical journals, and have brought the efforts of the members to the attention of a large circle of interested readers. Members of the profession or others having papers to present, or desiring to exhibit instruments, appliances or specimens are requested to send the titles of subjects as early as possible to

ALBERT N. BLODGETT, M.D., *Secretary*.
138 Boylston Street, Boston.

F. I. KNIGHT, M.D., *Chairman*.

OBITUARY. — DR. ALBERT H. CROSBY.

Dr. Albert H. Crosby of Concord, N. H., died suddenly of apoplexy at the house of his son-in-law, in Exeter, September 5. He was the eldest son of the late Prof. Dixi Crosby, and was born in Gilmanton, April 23, 1826. He graduated from Dartmouth College in 1848, studied law with his uncle, the late Hon. Nathan Crosby of Lowell, and at the Harvard Law School, and, after admission to the bar, practised in Francestown, N.H., and New York City. Law not proving congenial to his tastes, he returned to Hanover, and studied medicine under the instruction of his father, and received a degree from Dartmouth College in 1860. He located at Wells River, Vt, and removed to Concord, where he continued to reside until his death. In 1862, Dr. Crosby was appointed assistant surgeon of Columbus College Hospital, Washington, and was subsequently detailed as surgeon of the 13th regiment, Veteran Relief Corps, and was for a time one of the medical officers of the 6th New Hampshire regiment. In the latter part of 1863 he was assistant to his father in the medical bureau of the provost marshall's office of New Hampshire, and the following year was appointed post-surgeon, with headquarters in Concord. Dr. Crosby was one of the local board of medical pension examiners nearly all the time since the close of the Rebellion, physician to the State-prison for sixteen years, member of the school board and physician to St. Paul's school for many years. He was one of the most eminent physicians and surgeons in the State, his services in consultations being in great demand.

The Prevention of Insanity. By Gustavus Eliot, A.M., M.D., New Haven, Conn. (Reprint.) Hartford, Conn. 1886.

Electrolysis in Gynecology; with a Report of Three Cases of Fibroid Tumor successfully treated by the Method. By Franklin H. Martin, M. D., of Chicago, Professor of Gynecology in Chicago Polyclinic, etc. Read in the Section of Obstetrics and Diseases of Women at the Thirty-Seventh Annual Meeting of the American Medical Association, May 5, 1886. With Discussion by Ely Van de Warker, of Syracuse, N. Y.; Robert Newman, of New York City; George F. Hulbert and George J. Engelmann, of St. Louis, Mo. Also Supplementary Paper citing Two Cases of Fibroid Tumor treated by Electrolysis, by J. N. Freeman, M.D., of Brooklyn, N. Y. Chicago, 1886. (Reprinted from the Journal of the American Medical Association, July 17 and 24, 1886.)

Original Articles.

THE EFFECTS OF MILITARY DRILL ON BOYS.[1]

BY PROF. D. A. SARGENT, M.D., OF HARVARD UNIVERSITY.

LONG before the Civil War, many of the Southern States were pursuing the European plan of having State Academies devoted to military science.

At the outbreak of the Rebellion, while the North was obliged to look to the small nucleus graduated from West Point for its officers, the South had, in addition, the well-trained students of the State colleges to command its regiments. In the opinion of military men, the early successes of the Southern army were largely due to this fact.

Many of our Northern citizens were so much impressed with the utter lack of military training on the part of our educated young men at the beginning of the war, that efforts were made as early as December, 1861, to introduce infantry drills in the public schools. The matter was acted upon by the New York and other City Boards of Education, and referred by them to special committees. In the January following, Governors Andrew and Morgan recommended legislative action on the subject.

In 1863, military drill was established in the Boston schools. At the termination of the war, it was considered desirable by the general government that some of the army officers not otherwise employed should be detailed to teach the students of such colleges as desired it, so that educated men might have a better knowledge of military discipline and drill than they have hitherto had in these institutions.

Many of our schools and colleges applied to the government for officers, and entered upon the experiment of making military drill a part of the regular curriculum. How far this experiment has succeeded from the military point of view, I must leave those who are interested in our volunteer militia to answer.

I simply wish to call your attention to the fact that the primary object of establishing the drill in our schools and colleges was a professional one — that is, to give instruction in military tactics to educated young men, in order that they might be of service to the country or community in case of an emergency. The war gave an incentive not only to the practice of military drill, but it also furnished a great stimulus to all forms of physical exercise, and especially to athletic contests and games.

Within the past few years, physical training has received a new impetus. A large number of school, college, and city gymnasia have been built, and athletic games have obtained a strong hold on public attention.

As the occasion which gave rise to a call to arms grows more remote, and the real object of the drill loses its significance, the advocates for its maintenance in the schools claim for it superior advantages as a physical exercise. In the city of Boston, the committees to whom the subject of military drill in schools has been referred have placed considerable stress upon this point.

Allow me to quote a few lines from their published reports, as compiled by the Principals of the public Latin and High Schools for boys. In 1873 the Committee reported as follows:

"Your Committee believe that the drill, as now carried on, proves to be not only the *best* for physical exercise for these schools, but that, at the same time, it inculcates a more manly spirit in the boys, invigorates their intellects, and makes them more graceful and gentlemanly in their bearing."

In the report for 1874 there is a similar statement. In 1875 the Committee state:

"We trust that the drills will be kept up, believing that committees having them in charge will see that no form of gymnastics could be substituted from which the boys would derive such benefit."

In 1880 the Committee say:

"The establishment of the military drill is one of the few provisions made by the School Board for the physical training of the pupils under its charge, and no one who has observed the soldierly bearing of the members of our school battalions can have any doubt of its value as a means of securing a full and symmetrical development of the physique."

Notwithstanding the fact that half of the members of these committees were physicians, I shall beg to differ with them absolutely as to their conclusions concerning the physical effect of the military drill upon boys.

In order that we may approach the discussion of this subject more intelligently, let us inquire briefly into the physiology of exercise, and consider some of the facts which observation and experience have determined.

Exercise in its simplest sense may be defined as muscular movement produced by muscular contraction. According to the physiologists, "the property of contractility is inherent in the muscular substance, but in normal life the manifestation of this property is immediately determined through the influence of the nervous system. . . .

"A nervous impulse originating at the brain or spinal column travels along the nerves to their terminal expansions in the muscular fibres; on its arrival at the muscular fibre, the nervous impulse is converted into a muscle-impulse. . . . Between the reception of the nervous impulse and the initiation of the visible contractile movement an interval elapses, known as the 'latent period,' which (according to Helmholtz) is probably occupied by molecular changes in the fibre preparatory to its alteration in form. At the close of the latent period the muscle-impulse is succeeded by a wave of contraction. . . . The contraction of the individual fibres produces changes in form of the entire muscle, shortening the distance between its two extremities by increasing its thickness, and slightly reducing its bulk.

"In the voluntary muscles (according to Weber), each contraction is compound in character, being composed of a series of rapid contractions, due to an equally rapid succession of nerve-impulses."

During muscular contractions certain chemical changes take place in the muscle substance, although the exact nature of the metamorphosis is not known. It is known, however, that the blood escaping from muscles in action is much darker than the venous blood of muscles in repose, and that it contains a much greater proportion of carbonic acid.

It is also known that a greater amount of oxygen is absorbed by the muscle during the period of contraction, and Gaskell's experiments have demonstrated that the flow of blood through muscle is increased at the time of its shortening.

[1] Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Massachusetts Medical Society, Suffolk District, June 8, 1886.

Thus we see that the simplest muscular movements involve a molecular change at the nerve-centre in which the movement originates, in the nerve-fibre that transmits the impulse, in the muscle-fibres that contract, and in the bloodvessels that dilate in response to the stimulation. The experimental researches in the physiological laboratory on a single muscle have given us an epitome of what should take place throughout the system at large, in order to realize the best results from exercise.

The consecutive action and harmonious relation of the nervous, muscular, and vascular systems must accompany every effort to improve the physique and render the individual energetic, healthy, and strong. How to attain this three-fold result is the problem that the instructor of physical training has before him.

If you lift your arm in this manner (flexing the arm at the elbow), it is because the biceps muscle contracts, but the fibres are not hard and tense, and there is little evidence of an increased circulation. This would be termed a movement — almost a passive movement — and is what might be first advised to restore efficiency to the arm of a paralytic, or to preserve a single group of muscles from atrophy. This is the basis of the Movement Cure as founded by Ling, of Sweden.

If you should contract the muscles of the arm rapidly and energetically, you would give exercise to nerve-centres and nerve-fibres, but the muscles would not be efficiently used, and the blood-supply would not be much augmented.

By pursuing this method, the nervous system can sometimes be improved and the muscles made responsive, but activity will be attained at the expense of endurance. This is the basis of the Delsart system of physical culture now so popular in the schools of elocution.

Now grasp a heavy dumb-bell or weight in the hand, and elevate it slowly to the shoulder. In so doing you bring about an energetic action of the flexor muscles, but the nervous system is not especially active, and though the bloodvessels of the arm are gorged with blood, the circulation is not much improved. By pursuing this method the muscles can be increased in size and strength, but the individual, though strong, will lack heart and lung power, and be constitutionally weak. This is the result of the Heavy Weight System as formerly practised and advocated by Dr. Winship.

Now if the arm is alternately contracted and relaxed while using a lighter weight, the blood in the arteries is pushed forward into the veins, and through the veins into the heart. When it arrives at the heart, that organ is stimulated to contract with greater energy, and a proportionally greater amount of blood is sent back to the arm. In following this course, the bloodvessels in the parts used would be greatly increased in size and capacity, but in case many muscles were called into play at the same time, the brain and central nerve system would lack their due share of blood, and power to continue the effort for any length of time would be wanting. This, in a word, is the chief defect in the system of Light Gymnastics, advocated so fervently some twenty years ago by the late Dr. Dio Lewis.

These four methods of exercise, when elaborated and applied to the whole body, represent, I say, the fundamental principles of four great systems of physical training, each method being admirably adapted to meet the special wants of certain individuals, but wholly unreliable, and in many cases followed by fatal consequences when applied indiscriminately to all classes in the community.

To select at once a system of exercise that will do no harm to any one, and yet be beneficial to all, is a difficult task, yet we shall come nearer doing the greatest good to the greatest number if we follow what may be termed the physiological method. As near as I have been able to ascertain them, the essential requisites of a good exercise may be summed up in the following suggestions:

(1) The person should be sufficiently interested in the exercise to give it his attention in order to secure the necessary volitional power to start the movement. Any exercise executed in a lifeless way is of little benefit to nerve or muscle in a healthy condition.

(2) There should be a weight or resistance to overcome in order to bring out the working force of the muscle, the theory being that the muscles were not created merely to move the parts to which they are attached, but to do service and help man bear his burdens. In using a weight, the muscle gradually acquires the force with which it tries to contract.

(3) The exercise must be performed with sufficient vigor and rapidity to engage the energetic contraction of the muscles employed. When this is done, old tissue is broken down, and its place is supplied with new material in increased quantity, thus augmenting the size and strength of the muscles. The rapidity of the movement puts a limit to the weight used, and the alternate contraction and relaxation of the muscles assists the circulation of the blood in the parts employed.

(4) As many muscles as possible must be brought into action in order to secure a full-orbed and harmonious development of the whole body. One-sided development is usually attained by robbing some other part of its just share of the body's nutriment. It is apt to be accompanied by a functional disturbance of one or more of the vital organs, by inducing malformations of the thorax, or it is likely to lead to the straining of parts that are weak, by gauging their strength by parts that are strong.

(5) A sufficient number of muscles should be called into action at one time to stimulate the action of the heart and lungs and increase the circulation and respiration. This is one of the most important considerations to bear in mind in regard to exercise. The more muscles a person can use at one time, and the more rapid and extensive the movement, the greater the muscular consumption of oxygen and elimination of carbonic acid. In order to sustain this activity in the muscles, a greater amount of oxygen must be taken in, and a greater amount of carbon-di-oxide must be given off from the system. This is accomplished through the respiration. "If a man walks one mile an hour, he breathes twice as much air as when lying down; if he walks four miles an hour, he breathes four times as much, and if six miles an hour, seven times as much." He takes out of this inspired air an increased ratio of oxygen, and eliminates nearly the same proportion of carbonic di-oxide during expiration. To keep up this increased respiratory activity and to aid the heart in removing the waste material and hastening forward the new, the limbs and walls of the chest must be absolutely free from any ligatures or constrictions. The slightest interference with the

action of the respiratory muscles at this time embarrasses the functions of the lungs and heart. The chief advantage of exercises that give employment to many muscles at one time is that by increasing the respiration and quickening the circulation, they improve the health and strength of all parts of the body.

(6) As a "latent period" precedes the contraction of a muscle, so a momentary period of rest should, as far as possible, precede movement in exercise. This is best secured where there is an alternation in the movements, as in walking, running, rowing, etc. All tetanized movements, such as holding weights, standing in a constricted position, etc., tend to impair the tone of the muscles by interfering with the nutrition of both muscles and nerves.

(7) The exercises of the young should be of such a composite nature as to bring about the co-operation and co-ordination of the muscles. This involves principally the training of the central nerve system. All gymnastic sports and athletic games that require skill, dexterity, coolness, courage, and presence of mind, are included in this list, and are exceedingly valuable to any system of physical training, as adjuncts in the development of character.

My principal objection to military drill as a physical exercise is that it does not to any extent meet the physiological demands of the body as set forth in the seven observations just referred to. In other words: It is not of sufficient interest as a means of physical development to arouse any moral earnestness and enthusiasm on the part of the boys. The exercise of the manual is not performed with sufficient force and rapidity to engage the energetic contraction of the muscles employed. It is essentially a one-sided exercise, bringing into excessive action the elevators of the right scapula, the deltoid, biceps, flexors of the fore-arm, wrist and fingers of the right side, while the other muscles, excepting the legs on parade days, do not get sufficient employment to keep them in good condition. It does not increase the respiration and quicken the circulation to a sufficient extent to secure the constitutional benefits that should accrue from exercise.

During the drill the clothing is buttoned close around the chest, and natural respiration is hindered. The muscles are not alternately contracted and relaxed, but are tetanized or kept in a state of prolonged tension. This, as we have seen, not only impairs the tone of the muscles used, but it also puts an additional strain upon the brain and nervous system at a time when both should be as much relieved as possible. Finally, the mere exercise of the manual of arms does not give sufficient breadth and scope of movement to secure the co-operation of the muscles, and as a training for the central nerve system, it is of little or no value.

Coolness, courage, presence of mind, and that rapid and responsible exercise of judgment in emergencies, so valuable to the man of business, as well as to the soldier, are not developed by the drill itself, though I will admit that other moral attributes, such as obedience, patience, fortitude, and forbearance, may be brought to a high degree of perfection. The community at large have long entertained the idea that there was something about military drill that made young men erect, or, as the committee have been pleased to term it, giving them a graceful and manly bearing.

I dislike to take from the drill one of the strongest attributes that has commended it to parents and teachers, but unless I have been misled in my observations, there is nothing in the drill itself that tends to make one erect or graceful. On the other hand, I am prepared to maintain that it tends to make him stiff and angular in his movements, as well as to droop and round his shoulders.

This fact was long since brought to the attention of military authorities, and a set of calisthenic exercises or free gymnastics have been incorporated into all of the treatises on military tactics, to correct this tendency. I refer to what is familiarly known as the "setting-up" drill. Upton says, in his manual of "United States Army Infantry Tactics": "As the importance of 'setting up' cannot be over-estimated, the exercises must be often recurred to, and all soldiers will be frequently practised therein."

Notwithstanding this recommendation, I have yet to learn of a single military school in this country, the National School at West Point excepted, where these exercises are practised assiduously. They are irksome and unpopular, like all corrective measures, and are consequently never insisted upon.

There is another method, commonly known as "tailorizing," by which youthful soldiers may easily acquire a full chest, square shoulders, and a straight back. The results may not be as enduring, but they help out on parade day, and undoubtedly contribute something to the "manly bearing" that is so often spoken of. The moral is: Do not waste your admiration over the military figure until you see it with its coat off.

In reference to the gracefulness that is thought to characterize the movements of young cadets, I can only say it is not the outcome of drilling and marching. The soldier is trained to square corners, straight platoons, and angular movements. Curves and embellishments are not encouraged in speech or in action. If you would account for the graceful poise of our National cadets, you must visit West Point in summer, and see them from one to two hours a day in charge of the dancing master.

Having considered at some length what the drill does *not* do for boys, let me invite your attention to a brief consideration of some of the things that it does do. Here let me forestall any impression that my previous remarks on this subject may have left, and state that I do not think that military drill, as conducted in the Boston schools, is injurious to a strong, full-grown, healthy boy, except in a negative way. That is, it does not furnish him the physical training he needs for the maintenance of vigorous health, and the acquisition of a complete or symmetrical development. But those of you who have had the pleasure of examining school boys, or of looking over their measurements or photographs, will bear me out in saying that the strong and well-developed boys are largely in the minority.

The pupils attending our public and private schools represent nearly every phase and condition in life. Some are well nurtured, others are not. Some have favorable hygienic surroundings at home, others are subjected to unhealthy influences. All bear the stamp of a good or bad inheritance, and the strong and weak points of the parents show themselves in the physique as readily as they do in mental characteristics.

As no two minds are alike, so no two bodies are

alike. But growing out of this great diversity of shapes and sizes, there is a figure around which nature tends to range those of a certain age, height, or weight (according as either is taken for the standard). This is termed the mean or typical boy for a given age, height, etc. Any marked divergence from this standard is readily detected by a casual observer. My attention was long since called to what I think may be termed the prevailing weaknesses or defects in the school boy's and student's physique.

These are a drooping of the head, flatness of the chest, narrowness of the waist, and an exaggeration of the normal or physiological curves of the spine, and I might add to this number, though it is not quite so common in boys as in girls, lateral curvature of the spine. These defects, I say, are so apparent, that it does not take a practised eye to detect them. They attract the attention at once of any one who cares to examine the figures.

The drooping of the head and flatness of the chest may be accounted for by the increased prevalence of myopia, tightness of clothing, and the pressure of the school desk or table on the lower ribs and sternum. The hollowness in the back is partly due to the fact that it is a compensating curve, but more probably attributable to the weakness of the trapezii, rhomboidii, serati, and latissimus dorsi muscles.

The smallness of the waist is undoubtedly largely due to inheritance, and to the fact that the youth of the present day make very little use of the muscles of the waist and loins. Lateral curvature of the spine may be caused in many ways; by defective seats, bad positions in writing and drawing, standing for a long time on one leg, carrying weights, or using one arm more than another, etc.

Personally, I do not put particular stress upon these malformations, if they can be discovered in time. Nearly all of them can be corrected by judicious exercise. If allowed to increase, however, they invariably lead to spinal disease, or to some functional disturbance of the heart, stomach, or lungs, followed sooner or later by structural changes in these important organs.

Whatever the original cause of these physical defects may be, the immediate cause is a weakness of the supporting muscles.

After the body has once acquired a bias in the wrong direction many exercises otherwise beneficial are likely to be injurious. Among this number are horseback riding, rowing, lawn tennis and military drill. In order that you may see how the last named exercise can prove injurious to imperfectly developed boys I wish to call your attention to the elastic nature of muscular tissue.

In order to be as brief as possible I shall simply quote extracts from the experimental researches described by Rosenthal on this subject, in his admirable treatise on "Muscles and Nerves."

"A muscle dissected from the body is easily extended by a weight, and is extended in proportion as the weight attached is heavier. . . . The law of elasticity for inorganic bodies is: 'The tension is directly proportionate to the length of the body extended and to the amount of the extending weights; and that it is also proportionate in inverse ratio to the diameter of the extended body.'" . . .

"It has been found, however, that soft organic bodies, like muscles, are capable of far greater extension than are rigid, inorganic bodies of equal length and diameter and under the application of equal weight. But the organic body also exhibits another peculiarity."

"If a weight is attached to a steel wire or some other similar body, the latter extends and retains its new length so long as the weight acts upon it; but as soon as the weight is removed the steel resumes its original length. It is not so in the case of organic bodies. When the weight is removed from an organic body it immediately becomes shorter, but does not entirely revert to its original length; it attains the latter very gradually and in the course of many hours. This phenomenon is known as the gradual extension of organic bodies." . . .

"Muscle, in common with all soft bodies, exhibits another variation from the bearing of rigid bodies. That is, muscles are comparatively more extensible by light than by heavy weights. For instance, if the extension of a muscle when carrying ten grammes is five millimetres, when carrying a weight of twenty grammes it is not ten millimetres but only eight; when carrying thirty grammes it is only ten millimetres, and so on."

Another striking fact in connection with the physiology of the muscles has been brought out by the experiments of Weber. He has proven conclusively that muscle is further extended by the same weight when it is in a state of activity than when it is quiescent. Here again we have the experiments of the physiological laboratory confirming the facts that have been brought under frequent observation in the gymnasium. We can now readily understand, how carrying the head forward would soon extend the muscles of the neck, how carrying a gun, though a light one, with the same arm for any length of time would gradually extend the muscles, and elongate the arm, droop the shoulder and crook the spine. This is, in fact, what military drill tends to do in all cases, and what it invariably does do when there is a bias in that direction, when the boy is tall and slender, or the muscles weak and flabby, and there is no effort made to correct the evil tendency.

If it is deemed advisable to make military drill a department of school instruction, I see no reason why a system of corrective exercises cannot be introduced as an accompaniment. If, on the other hand, military discipline alone is required, this can easily be applied to a system of class gymnastics or free exercises, as shown in the schools of Germany.

After taking the most favorable view possible of military drill as a physical exercise, we are led to conclude that its constrained positions, and closely localized movements do not afford the essential requisites for developing the muscles, and improving the respiration and circulation, and thereby improving the general health and condition of the system. We must further conclude that in case of any malformation, local weakness or constitutional debility, the drill tends, by its strain upon the nerves and prolonged tension on the muscles to increase the defects rather than to relieve them.

Finally, if the ultimate object of the drill was to prepare young men for the life and duties of a soldier, we should be forced to conclude that the drill itself would still be defective as a means of developing the chief requisites for men in that profession.

This defect, we are pleased to state, is recognized by the great military nations of Europe, and measures

are taken to give all the recruits from three to twelve months' gymnastic training to develop them as *men*, before they are expected to conform to the requirements of the soldier.

MILITARY DRILL AND GYMNASTIC TRAINING IN PHYSICAL CULTURE.[1]

BY E. M. HARTWELL, PH.D., M.D. OF JOHNS HOPKINS UNIVERSITY.

I FEEL some embarrassment in standing here as an advocate of the superiority of gymnastics over military drill as a means of physical training for schoolboys, since, in so doing, I am obliged to dissent from the views of General Moore, who was formerly my commanding officer. I suppose that as one of his orderly-sergeants in the Latin School Battalion, I passed the climax of my self-importance. I thought then that the drill was a very good thing. I think now that it did the other boys good, and that it did me good, but I am compelled to think, as the result of my reading, observation and experience, that while much good may be accomplished through military drill in boys' schools, very much more good can be attained through a well-devised and intelligently-managed system of gymnastics.

It is a noteworthy fact that physical training has always owed much to lessons learned in war. Under the sting of defeat, or the stimulus of victory, the most enlightened and the rudest nations have alike been impelled to give to bodily training a place in their schemes for the education of their youth. It was in the half century following the victories gained by the Greeks over the Persians, that Greek gymnastics saw their palmiest days. It was then that the gymnasia furnished the finest models for the noblest specimens of the sculptor's art. Although the Greek training was chiefly general and educational in its aims, it embraced certain exercises of a martial character. The Norman archers made such an impression upon the English at Hastings, that centuries elapsed before English law-givers ceased to legislate for the training of the people in "Shooting."

An English law passed in 1388 required servants and laborers "to have Bows and Arrows and use the same the Sundays and Holydays, and leave all playing at Tennis or Football and other Games called Coits, Dice, Casting of the Stone, Kailes, and other such importune Games." Henry VIII caused Parliament to enact, in 1511, that "every man being the King's subject, not lame, decrepit or maimed; being within the age of sixty years, except spiritual men, justices of the one bench and of the other, justices of the assize, and barons of the exchequer, do use and exercise shooting in long bows, and also do have a bow and arrows ready continually in his house, to use himself in shooting; and that every man having a man child or men children in his house shall provide for all such, being of the age of seven years and above, a bow and two shafts, to learn them and bring them up in shooting." Each village was, in 1541, required to maintain a pair of archery butts. It would seem that this statute was held to apply to school-boys and collegians. It is noteworthy that certain playgrounds at Eton and Harrow respectively, are still termed "the Shooting Fields" and "the Butts." The English took the lessons of the Crimean War so deeply to heart that, great as is their aversion to gymnastics, they introduced gymnastic drill into the army in imitation of their neighbors on the Continent.

The quickening and shaping influences of the Napoleonic Wars, of the War of Liberation, and of the wars with Austria and France, are clearly discernible as potent factors in the development and organization of the German system of physical training. France has, since 1871, organized an elaborate system of physical training, embracing both gymnastic exercises and military drill in connection with all its public schools for boys.

We in America occupy no exceptional position in this matter, unless it be that we are preternaturally slow to profit by the experience of other nations. The first attempts in America to promote physical training were of a military character. On January 21, 1790, President Washington transmitted to the first Senate of the United States a comprehensive report from General H. Knox, the Secretary of War, on a plan for "a national defense system adequate to the probable exigencies of the United States, whether arising from internal or external causes." The plan called for the enrollment of those liable to bear arms into three classes: the first comprehending the youth of eighteen, nineteen and twenty years of age, to be denominated the advanced corps; the second class including the men from twenty-one to forty-five years of age, to be denominated the main corps; the third class comprehending, inclusively, the men from forty-six to sixty years of age, to be denominated the reserved corps. It failed, however, of adoption, although the need of a well-trained militia had been sharply and abundantly emphasized by the events of the Revolutionary War. The failure was attributed to the great expense and the administrative difficulties which it was believed it would entail.

In 1792, a United States law was passed, which is still in force, I believe, requiring the enrollment of "all able-bodied male citizens of the respective States" between the ages of eighteen and forty-five years. All enrolled citizens are required to be "constantly provided with a good musket or fire locket . . . a sufficient bayonet and belt, two spare flints, and a knapsack, a pouch therein to contain not less than twenty-four cartridges . . . or with a good rifle, knapsack, shot-pouch, and powder-horn, twenty balls suited to the bore of his rifle, and one-fourth of a pound of powder." So far as I know, neither the Boston School Regiment, nor any other regiment, complies with the requirements of this law.

In 1817, in a report on the reorganization of the militia, made to the House of Representatives by Mr. Harrison, it was recommended that "military instruction should not be given in distant schools, but that it should form a branch of education in every school within the United States; *that a corps of military instructors should be formed to attend to the gymnastic and elementary part of education in every school in the United States*, whilst the more scientific part of the art of war should be communicated by professors of tactics, to be established in all the higher seminaries." It does not appear that this scheme, or anything like it, ever received the sanction of law, although it was again brought forward for adoption in 1819.

Meanwhile, the United States Military Academy at

[1] Remarks made at the meeting of the Section in Clinical Medicine, Pathology and Hygiene of the Massachusetts Medical Society, Suffolk District, June, 1886.

West Point, in New York, had been instituted for the professional training of army officers. Yet the bitter lessons of the war of the Revolution had to be enforced by those of the War of 1812 before Congress could be induced to make anything like adequate provision for such training.

At West Point, bodily training, under the heads of military instruction and sword exercise, has received marked attention from the first. Dancing is now regularly taught, and gymnastics and swimming have at times been regular branches of instruction. The United States Naval Academy dates from the year 1845. Both at West Point and Annapolis the course of study is characterized by an extended, varied, and exacting system of bodily exercise, as embraced in the various drills and branches of practical instruction. The absolute control and constant supervision and inspection to which all cadets are subjected, as regards deportment, dress, studies, exercise, recreation, diet, and rest, are productive of a vigorous manliness which is much less uniformly found in the graduates of other institutions.. I am strongly convinced that the best that has as yet been accomplished in the United States in physical training has been accomplished at West Point and at Annapolis, but nothing can be clearer than the fact that only a very small part of the training there in vogue is what is understood as military drill in the Boston schools.

Alden Partridge, captain of engineers in the United States Army, who was for a time Superintendent of the Military Academy, seems to have been the first person to found an institution modelled after that at West Point. Captain Partridge left the Military Academy in 1817, and in 1818 resigned from the military service of the Government. In a lecture delivered by him in 1820 on what he conceived to be the deficiencies of superior education as then conducted, Captain Partridge spoke as follows:

"Another defect in the present system is the entire neglect, in all our principal seminaries, of physical education. The great importance and even absolute necessity of a regular and systematic course of exercise for the preservation of health, and confirming and rendering vigorous the constitution, must be evident to the most superficial observer. That the health of the closest applicant may be preserved, when he is subjected to a regular and systematic course of exercises, I know from practical experience; and I have no hesitation in asserting that in nine cases out of ten it is just as easy for a youth, however hard he may study, to attain the age of manhood with a firm and vigorous constitution, as it is to grow up puny and debilitated, incapable of either bodily or mental exertion."

Captain Partridge opened his American Literary Scientific Academy at Norwich, Vt., his native town, September 4, 1820. In 1825, he removed his seminary to Middletown, Conn., where he remained for three years. He was doubtless impelled to abandon his seminary there from the refusal of the legislature of Connecticut to charter the institution as a college. He was instrumental, in 1834, in rehabilitating the institution at Norwich, which became known as "Norwich University," and in establishing military schools at Portsmouth, Va., in 1839, at Brandywine Springs, Del., 1853, and at Bristol, Pa., in 1853, the year of his death.

A considerable number of military schools and colleges, additional to those above mentioned, were organized before the War of the Rebellion. The more important of them were established in the Southern States, and were in several cases subsidized by the State. This was notably the case in Virginia, South Carolina, Louisiana, Kentucky, and Alabama. The Virginia Military Institute, at Lexington, Va., the Military Institute at Frankfort, Ky., and the Louisiana State Institute, at Alexandria, La., should be mentioned in this connection. It has been estimated that "one-tenth of the Confederate armies was commanded by the *élèves* of the Virginia Military Institute, at Lexington, embracing 3 major-generals, 30 brigadier-generals, 60 colonels, 50 lieutenant-colonels, 30 majors, 125 captains, 200 to 300 lieutenants." General "Stonewall" Jackson was long a professor in the Virginia Military Institute. General W. T. Sherman, of the United States Army, was in 1861 the head of the Louisiana State University, which had been organized on a military basis in the previous year. At the North the military plan of education was chiefly adopted by the proprietors of private schools for boys.

Once the war opened, military drill assumed a new and unprecedented interest in the eyes of school authorities. The educational literature of that period teems with schemes for the introduction of gymnastics and military drill into public school courses. As early as 1861 military drill was introduced into a portion of the public schools in the city of Bangor, Me.; and the State of New Jersey, about the same time, made an appropriation of money for military instruction in her normal school.

Elementary military drill was experimentally introduced into the Public Latin, English High, Eliot, and Dwight Schools for boys in Boston in 1863. It has since been eliminated from the grammar schools, to which class the Eliot and Dwight belong, but has been introduced into all the high schools of the city for males.

There are not far from sixty schools and colleges, in various parts of the country, in whose course of instruction military drill is given a prominent place. Public schools are not included in this number; but in nearly half of the number the military drill is in charge of an Army officer, specially detailed in accordance with Morrill Act of 1862, whose purpose was to promote the organization of State Mechanical and Agricultural Colleges.

The aim of the school system of Boston is, I take it, a general one, namely, to prepare boys and girls to enter with profit, at a later stage of their development, upon courses of special training for their life work, and the question under discussion is not whether military drill, by itself considered, is helpful or harmful, but whether so much of military drill as is laid down for a portion of the school-boys of Boston constitutes an adequate system of physical training.

I freely admit that the setting up drill, the manual of arms, and the marching movements as taught by General Moore are valuable; that they promote healthful growth and development to a limited degree; and that they subserve certain ends of mental and moral discipline. But I hold that they are so narrow, unnatural, and technical that they cannot be made to meet the legitimate demands of a sound system of general physical training. Such gymnastic exercises as you have witnessed here this evening demonstrate very satisfactorily, it seems to me, the superiority of

gymnastic to military drill. But it should be borne in mind that these exercises constitute but a small portion of the exercises which are comprised in any system of school gymnastics worthy to be so designated. It need hardly be said that no comprehensive system of gymnastics has ever been attempted in the Boston schools. No city in the United States, unless it be Kansas City, in Missouri, has as yet worked out or adopted a system of school gymnastics that will bear comparison with the systems now in vogue in the schools of the principal cities of Germany, Sweden, and Norway, France, Switzerland, and Austria.

It will be best to confine our attention to the German system of physical training, and more especially to that in vogue in Prussia.

The German for gymnastics is *Turnkunst* or *Turnen*. *Turnplatz* and *Turnhalle* correspond respectively to our terms out-door gymnasium and gymnasium, which latter ordinarily signifies a building for gymnastic exercises. A gymnasium, in the German sense, is the highest of the secondary schools, and leads directly to the University.

German gymnastics embrace three well-marked fields, or departments, namely, *Volksturnen*, or popular gymnastics; *Schulturnen*, or school gymnastics; and *Militärturnen*, or military gymnastics. The organization of the last two departments is maintained and controlled by the Government for strictly educational purposes; whereas the *Turnvereine*, as the societies of the turners are called, are voluntary associations of a social and semi-educational, but wholly popular and patriotic, nature. The germ of the turning system is to be found in the martial games and exercises of the ancient Teutons.

Volksturnen was the first to develop. It had its beginning in the period of Prussia's deepest distress and humiliation,— the period between the victory of the French at Jena, in 1806, and the War of Liberation in 1813. That turning became a popular institution and a potent factor in the development of Prussia was largely due to "Father Jahn," as the turners call him.

Jahn was an ardent patriot. His strong and rugged nature, and his eager, restless, passionate spirit, qualified him for popular leadership in the movement which he initiated. He seized the idea of making bodily training a force in national regeneration and education, and dreamed and wrote and labored for a free and united Germany.

The turners did notable service in the campaigns against the French, and great enthusiasm for gymnastics was kindled all over Germany. From 1819 till 1842 the turnvereine, as the gymnastic societies are called, were not suffered to exist by the Government.

In April, 1842, the ministers of war, the interior, and education, united in recommending to the King of Prussia the re-introduction of turning. In June following, the King gave his sanction to the proposal of his ministers that "bodily exercises should be acknowledged formally as a necessary and indispensable integral part of male education, and should be adopted as an agency in the education of the people." The King also authorized the establishment of "gymnastic institutes," in connection with "the Gymnasien, the higher middle schools, the training schools for teachers, and the division and brigade schools in the army."

The great majority of German turnvereine have, since 1860, belonged to the organization known as the *Deutsche Turnerschaft*.

The Turnerschaft comprises fifteen circuits, or geographical divisions, within the German Empire and Austria. Each circuit is subdivided into districts (*Gaue*), and each district into societies (*Vereine*). On January 1, 1885, there were 220 *Turngaue* within the Turnerschaft, and the number of vereine within the Turnerschaft was 2,878, an increase of 223 over 1884. The membership in 1885 was 267,854, of whom 114,134 were active turners; or to express it differently, in 2,413 localities there was an *active* member of the Turnerschaft for every 134 of the population. In 1884, 2,409 societies practised winter turning, 353 owned a turnplatz, and 182 owned a turnhalle.

The aim of the Turnerschaft is to promote the interests of turning, as a means to bodily and moral strength. Its members are urged to render turning attractive to boys and apprentices who have passed the school age; to cultivate simple German customs and manners; to cultivate national exercises and games, such as free and class exercises, running, leaping, climbing, casting the weight, hurling the spear, wrestling, fencing, and sword play; to participate in all popular festivals, especially those commemorative of national events, such as the Kaiser's birthday, Sedan day, and the like; to manifest an active interest in useful public enterprises and associations, such as fire and salvage companies, and sanitary corps for the care and transportation of the sick and injured.

The turners are divided into two main sections, namely, boys from fourteen to seventeen years of age, and men. These divisions are subdivided according to their gymnastic ability into squads, or classes, each class being under the lead and guidance of a "foreturner" chosen on account of fitness. Strength alone is not enough. It is the foreturner's business to make his squad as expert as possible, and above all, to secure to each of its members an erect, firm, and graceful carriage of the body.

The General German Turning Festival, as the grand festival of the entire Turnerschaft is termed, occurs at intervals of at least four years. It continues for at least three days, one of which must be Sunday. Six such festivals have been held in different German cities since the first was celebrated at Coburg in 1860. The Sixth German Turning Festival was celebrated at Dresden, July 18–23, of last year. I was so fortunate as to be present during its continuance.

The festival was characteristically German in its object, arrangements, and detailed workings. In the opinion of competent judges a very considerable increase in gymnastic proficiency over that exhibited at any former festival was noticeable.

More than 20,000 turners, including delegations from England, France, Russia, Holland, Switzerland, Austria, Hungary, Sweden, and the United States took part in the street parade, which was reviewed by the King of Saxony from a balcony of his palace on Sunday, the first day of the festival. The grounds set apart for the use of the turners were something more than ten acres in extent, and were situated in the outskirts of the city, adjoining the Grosser Garten, the principal park of the King. Chief among the temporary buildings erected on the Festplatz was the festivall hall, with an estimated capacity for 10,000 people. The main part of this hall was left unfloored, so that in case of unfavorable weather all the heavy gymnas-

tics might take place under cover. As the weather was fine during the entire continuance of the festival, the hall was used chiefly for speech-making and merry-making, and the turning of every description was carried on out of doors on the Turnplatz, which had an area of more than three quarters of an acre.

The most noteworthy gymnastic features of the festival were: The free gymnastics; the class turning of the most proficient turners; the prize turning, and the gymnastic games in which 1,600 girls and 1,200 boys belonging to the Dresden School took part.

The free gymnastics are bodily movements arranged in groups of related exercises, which are executed at command and in unison. In them no apparatus of any kind is made use of. They may be characterized as calisthenics raised to their highest power. The free gymnastics on this occasion included sixteen different movements, and required nearly three-quarters of an hour for their completion. The order and character of the movements had been determined and ordained by the proper committee of the Turnerschaft months before, and the movements had been practised by the different vereine at home, but only there. The turners who took part in the free movements numbered 4,544, and were formed in seventy-one "open ranks" of sixty-four men each, facing toward the front, the distance between the "files" being a full arm's-length. Facing the huge class was a high platform, on which two marvelously expert foreturners first executed each movement in sight of the class, and then, at signals given with a flag by the turnwart in command of the class, and re-enforced by strokes given on gongs in the middle of the field, the foreturners repeated the movement, the entire body of 4,500 men following in unison. The sight of 4,500 bareheaded, white-shirted men, many of them grayheaded, executing complicated movements, which involved tossing of the arms, bowing and bending of the trunk, facing now this way and now that, and all with military precision, in nearly perfect time, was a novel and inspiring one. Would that those who belittle gymnastics as a means of discipline could have seen the marching and facings of that class of 4,500 men.

The essential differences between Volksturnen and Schulturnen are based on the fact that the former is a free art, originating with and maintained by the common people, and the latter is a discipline imposed by authority upon persons in a state of pupilage. The ends of training and education are not lost sight of in Volksturnen, but in Schulturnen they occupy the foreground.

As regards physical training in the schools of Prussia, the case stands thus: Attendance upon instruction in turning is exacted of all unexcused pupils for two hours weekly in all schools for boys, and also, in some cities, in all schools for girls. As a rule, each school has its own turnhalle, and in very many cases its own turnplatz, furnished with appropriate gymnastic machines. Some cities, for instance Frankfort-on-the-Main, provide special playgrounds for the use of school children and instruction in swimming.

While gymnastic drill is not universal in the public schools, it is very general. As might be expected, it is more common and better provided for in the cities than in the country. In 1882 only ten per cent. of the pupils in the higher schools for boys were excused from turning, and they were excused on the certificates of physicians that the exercise would be prejudicial to their health; only eighteen per cent. of this class of schools were obliged to discontinue turning in winter through having no proper turnhalle, and sixty per cent. of them possessed a turnhalle.

In the course of study each class has its special time for gymnastics, just as it has special hours set for arithmetic and reading, and in the majority of cases the instruction is given by one of the ordinary class teachers, and not by a special teacher of turning. The amount of time devoted to turning, singing, and drawing, is usually the same, viz., two hours weekly.

The exercises are carefully adapted to the age, strength and sex of the pupils. The youngest pupils, from six to ten years old, engage in a great variety of simple games, easy, free movements, marching, jumping and climbing exercises, and the fundamental exercises on the easier gymnastic machines. In free, light, and heavy gymnastics the exercises grow more complicated and difficult with the advancing age of the pupil. The expertness of the boys in the upper classes is often quite astonishing. In the Gymnasien and Realgymnasien fencing is taught in the upper classes. Pedestrian tours, skating parties, and excursions into the woods are frequently made under the lead of those who teach turning. The gymnastic course for girls comprises the ordinary free gymnastics; class gymnastics with "hand apparatus," such as dumb-bells, wands, and skipping ropes; marching, dancing, and balancing exercises; various games of ball, easy jumping, swinging, and climbing; and a few of the simpler exercises on the parallel and horizontal bars. Singing, especially during the march and the minuet, is frequently engaged in during the hour given to gymnastic instruction.

The population of Berlin in 1880 was 1,122,330. The total number of pupils in schools of every kind in the city was more than 149,000, of whom not more than 25,000 were in private schools. In schools wholly maintained at the city's expense, there were 104,726 pupils. Of the 62 turnhallen belonging to the city, 41 had turnplätze adjoining or near to them; 2 belonging to higher schools for girls; 11 belonged to higher schools for boys; and 48 belonged to schools of the grade of Volksschulen (termed in Berlin *Gemeindeschulen*); and 1 belonged to the Berlin Orphan Asylum. The city paid nearly $50,000 in 1880–81 for the instruction given its school children in gymnastics, which sum is equal to about one twenty-third of its total expenditure for schools in that year.

The present number of city turnhallen used for educational purposes in Berlin is 98. The largest of them is the *Städtische Turnhalle*, in the Prinzenstrasse. This was established in 1864; it is open every day and evening, and is used at appointed times by several of the Berlin turnvereine, also by the association of Berlin teachers, the royal firemen, the normal classes for teachers of turning, and by eight of the city schools for school turning. In all, more than 13,000 persons exercise here weekly. The annual appropriation for its maintenance, exclusive of salaries, is between $2,500 and $3,000.

As a rule, the school gymnasia in Germany are separate and specially designed buildings, and not refitted rooms. As a class, the German gymnasia are not so luxuriously fitted or so architecturally imposing as many of the newer American college gymnasia, but they are admirably adapted to the purpose of teaching

of free and class gymnastics of every description. As much as possible the apparatus is adjustable and portable. A plain, one-story, brick turnhalle, 60 by 33 feet and 15 to 20 feet high, can be built in Germany at a cost of $5,000, and well furnished with apparatus for $1,000.

In this connection the following facts regarding the Volksschulen of Vienna may be of interest: In 1882–83 Vienna, whose population in 1880 was 704,756, had 72,912 pupils in its 135 Volksschulen. Of this number 44,614 (21,047 of whom were girls) practised turning under the guidance of 658 teachers. The city paid for the teaching of turning and the care of the turnhallen in 1882–83, a sum equal to $34,860, or one-twenty-ninth as much as its total ordinary expenditure for the Volksschulen.

The Prussian schools and the Prussian army are admitted to be the best of their kind. It is a fact of capital importance that in the foremost military State of all the world, not only is military drill excluded from the system of public instruction, but it is also held to be insufficient for purely military purposes, and an elaborate system of gymnastics has been adopted for the training of the soldiery. Even in the cadet schools, boys under fourteen years of age are not allowed to drill with muskets. In Prussia as in other parts of Germany, it has often been proposed to make military drill a part of the instruction for boys. The proposition has been widely and fully discussed, but the weight of the best opinion, educational and military, have been against it. Such experiments as have been made in the direction of giving the schools a military character have not succeeded. On physiological, educational, and military grounds, the authorities prefer gymnastics to military drill, both as a means of securing the symmetrical development of the bodily powers, and as a preliminary training for efficient service in the army. Military drill, say the best of the Germans, is, if genuine, too stiff and severe for school boys; while, if it be not genuine, its moral effects are bad and its tendency is towards the formation of vicious habits of carriage and movement.

Gymnastics and military drill have been made obligatory in practically all public schools for boys throughout the French republic. It is a little more than four years since the French government passed a law requiring the enrollment of all able-bodied boys over twelve years of age in the so-called *bataillons scolaires*. The boys wear a sort of uniform, and are dubbed with muskets, and figure with the rest of the troops on July 13th, the day of the National Festival.

The Germans look with disfavor, but not with fear, upon this movement of the French. It is somewhat too early to pronounce upon the success of the experiment, but there are indications that it is not fulfilling the claims of those who were instrumental in causing it to be made. One of the French military journals characterizes the movement as "a useless phantasmagoria," and General Millot says: "Do not let childhood play at soldiering. The musket should not be taken in hand too soon. It is only in the barracks that the military training of a young man is properly given. Train gymnasts for us; our officers and under-officers will soon make good soldiers of them."

The best exponent of the German system of training in this country is the North American Turnerbund, which comprises more than two hundred societies or *Vereine*, and has a total membership of more than 21,000. In the Turnschulen of the Bund, 12,228 boys and 4,005 girls received instruction in gymnastics in the year 1884–85. It is very remarkable that the ignorance of American educators should be as dense as it is regarding the aims and achievements of the Turnerbund, which has maintained a special Normal School for the training of teachers of turning for many years in the city of Milwaukee. Yet the fact is that the Turnerbund owns more gymnasia than all the colleges of the country put together, and its corps of trained and salaried teachers, numbering nearly one hundred, is the best the country affords.

The German system of school turning embraces free movements, light gymnastics, and heavy gymnastics, all of which may easily be taught to school or college classes, provided you have competent teachers and a well-equipped gymnasium. The German system of physical training is a practical system, based upon sound physiological and pedagogical principles. It is managed by specially-trained teachers, who have perfectly definite ends in view, and its results are admirable. The average American college boy compares, as regards educated bodily ability, with his contemporaries in the upper classes of the gymnasium of Berlin and Frankfort, as do children who can print and one learning to write with the most accomplished pupils of drawing in your city schools.

If the School Committee of Boston shall ever really undertake to provide for the physical training of those committed to its charge, it will do well to profit by the example and experience of such enlightened States as Prussia. To do so it must bring gymnastic training for boys and girls to the front, and send military drill to the rear, or abolish it altogether.

RECENT PROGRESS IN DISEASES OF THE NERVOUS SYSTEM.

BY PHILIP COOMBS KNAPP, M.D.

PROGRESSIVE ATROPHIC MYOPATHY.

Recent investigations have shown that there was a certain amount of truth on either side in the dispute that was once waged over the essential nature of progressive muscular atrophy. The spinal nature of the atrophy of Duchenne-Aran is now well established, but the recent work of Landouzy and Dejerine[1] shows that there is another form of progressive muscular atrophy which is essentially a pure myopathy. They have made a careful study of six different cases, occurring in two different families, and give a report of the autopsy in one case. In one family there had been nine cases in five generations, in the other two cases in three generations; the affection thus manifesting a distinctly hereditary type.

The disease usually begins in early childhood, making its first appearance about the age of three or four, but it may come on later in life. If it begins in childhood, the muscles of the face are first involved, the face seems to have a mask over it, the forehead is smooth, the wrinkles are abolished, the eyes seem wider open, and are not perfectly closed, and the lips protrude. The child has a dull, expressionless look, almost like that of an imbecile, although the intellec-

[1] L. Landouzy et J. Dejerine. De la myopathie atrophique progressive, myopathie sans neuropathie, débutant d'ordinaire dans l'enfance par la face. Revue de Médecine, Feb., April, 1885.

tual faculties are unimpaired. Any attempts at the expression of emotion intensify the condition, the laugh being especially characteristic. The affection may remain confined to the face for years, but later on the process involves other portions of the body. The shoulder and upper arm are next attacked, the process involving the trapezius, the rhomboids, the deltoid, the biceps, the brachialis anticus, the triceps, the supinator longus, the pectorals, and the flexor carpi radialis. The thenar group are less frequently attacked, the abductor brevis being first affected. When the atrophy is extensive, the hand assumes the simian type, the *main en griffe* being rare.

In adults, the process may begin in the shoulder, the face remaining intact. Later on the lower limbs are affected, first the thigh, and later the leg, the foot assuming a position of equinus. The abdominal muscles and the sacro-spinalis also atrophy, and there may be lordosis. The subscapular, infra and supra spinales, and the flexors and extensors in the fore-arm remain free for a long time; and the muscles of mastication, of the eye, tongue, palate, and pharynx are never involved. There is never any hypertrophy or pseudo-hypertrophy. A slight retraction of certain muscles, like the biceps, preventing complete passive extension of the fore-arm, is often seen, and is very characteristic. There are never any fibrillary contractions in the muscles, such as are often seen in myelopathies. Electrical excitability disappears, along with the voluntary contractility, only when the muscle is wholly atrophied. The changes in the electrical reaction are never qualitative, but only quantitative — that is, there is never reaction of degeneration. The patellar reflex stands in direct ratio to the amount of unatrophied muscle. General and special sensibility remains intact; there is never any trophic disturbance; the sphincters and the muscles of vegetative life remain intact throughout.

The affection is essentially chronic, but continuous in its march. The victims of it may live for thirty years, but are apt to die of tuberculosis. In the case which came to autopsy, and which died of phthisis, there was absolutely no change in the central nervous system or in the peripheral nerves, even in their finest muscular branches. The only lesion was a simple, progressive atrophy of the primitive muscular fibre, with some sclerosis and a little adipose deposit. Occasionally a few fibres were hypertrophied, but this was not extensive enough to be evident clinically. When an individual muscle was attacked, it was attacked in all its parts, but certain muscles remained unaffected. The process is regarded as a primitive parenchymatous myositis, leading to atrophy, and combined with a very slight interstitial myositis. It is regarded as an atrophic cirrhosis, whereas pseudo-hypertrophic muscular paralysis is a hypertrophic cirrhosis. The fact that the finest nerve-fibres remain intact effectually demolishes Friedreich's theory that the nervous lesions in progressive muscular atrophy, type Duchenne-Aran, are deuteropathic, secondary to the atrophic changes in the muscle.

The diagnosis is not difficult if all the above points are considered. The chief disease to be excluded, of course, is the Duchenne-Aran type of atrophy. In this form the face is never involved; it is apt to begin in the hand; it affects adults; the muscles show fibrillary contractions; there are no muscular retractions, and definite groups of muscles are involved; this form, too, has never yet been seen in infancy. In amyotrophic lateral sclerosis there is more paralysis than atrophy, and when the face is involved, bulbar symptoms appear. Anterior poliomyelitis is not as slowly progressive, never involves the face, and shows reaction of degeneration. Erb's juvenile form of muscular atrophy is attended with some hypertrophy, and never involves the face. Pseudo-hypertrophic muscular paralysis begins in the lower limbs, and is attended with marked hypertrophy.

NEURITIS.

Pitres and Vaillard[2] have recently been making careful studies of the changes in the peripheral nerves in various infectious diseases. Among the nervous sequelæ occasionally seen after typhoid fever, are paralyses of one or more groups of muscles, which are in all probability due to a lesion of the peripheral nerves. These paralyses may be attended with pain, anæsthesia, loss of electrical excitability, and atrophy. In one case the peripheral nature of the trouble, which had seemed probable from the symptoms and course of the paralysis, was proven by an autopsy. Histological examination of the nerves in patients who have died of typhoid fever has shown that the peripheral nervous system is often the seat of the more or less grave and diffuse alterations of parenchymatous neuritis. If these changes are slight, the trouble may remain latent, or else the changes may give rise to only a few vague signs; but with more pronounced changes the sensory, motor, and trophic disturbances characteristic of neuritis appear, and, after some cases of typhoid, may be well marked.

In the course of tuberculosis, too, parenchymatous alterations — a degenerative neuritis — are not infrequently found in the peripheral nerves, originating in them and independent of any lesion of the brain or cord. This degeneration may attack motor, sensory or mixed nerves, and even the cranial nerves, or nerves like the phrenic and pneumogastric. The symptomatology of these affections is complex, but the authors make three divisions: 1, *névrites latentes*, where the lesions are slight, and the nervous symptoms are latent or escape observation from the severity of the tuberculosis; 2, *névrites amyotrophiques*, where the most prominent symptom is atrophy; 3, *névrites douloureuses ou anesthetiques*, where sensory troubles, pain, anæsthesia, hyperæsthesia, and paræsthesia predominate. The frequency and the variations in the distribution and symptomatology help to explain the existence and the polymorphism of many of the nervous troubles in tuberculosis.

In one case of neuritis, involving several nerves, coming on in a tubercular patient after cutaneous diphtheria, a curious change was noted. The degeneration, which did not differ essentially from the parenchymatous degeneration ordinarily seen, attacked only certain segments of the nerve-fibre, *névrite segmentaire*, so that a single fibre would show several centimetres of degeneration between two portions of healthy fibre. Sometimes two or three such segments could be seen in a single fibre, and the degeneration was not peri-axial, but involved the axis cylinder, and completely

[2] A. Pitres et L. Vaillard. Contribution à l'étude des névrites périphériques survenant dans le cours ou la convalescence de la fièvre typhoide. Revue de Médicine, December, 1885.
— Des névrites périphériques chez les tuberculeux. Revue de Médicine, March, 1886.
— Contribution à l'étude de la névrite segmentaire. Archive de Neurologie, May, 1886.

destroyed it. Other fibres showed a continuous degeneration throughout their course. The authors were unable to explain this peculiar change, or to reconcile it with the law of Wallerian degeneration.

Gombault [5] has described a different form of segmentary neuritis, where the axis-cylinder can be traced through the affected part, and is directly continuous with the healthy axis-cylinder. It is not normal, however, but is swollen and flattened. He states elsewhere [4] that this peri-axial segmentary neuritis either recovers or progresses, involves the axis-cylinder, and thus leads to Wallerian degeneration. Hence, he calls it a pre-Wallerian stage of degeneration.

Buzzard [5] reports cases of local paralysis, associated with pain, tenderness over the nerve-trunks, anæsthesia, paræsthesia, and changes in the electrical reactions, in patients who have previously shown decided symptoms of gout, and he considers the symptoms due to a neuritis brought on by the irritation of the nerve-fibres by the urate of sodium in the blood. He also reports cases following syphilis, tuberculosis, typhoid, etc. Oppenheim,[6] reporting a case of multiple neuritis of doubtful origin where there were decided mental symptoms, claims that the most important causes of the disease are cold and alcoholic excess. Francotte [7] reports four cases of multiple neuritis, three in alcoholic or tubercular subjects and one in a previously healthy individual. Eulau [8] reports a similar case in a man previously healthy, where it seemed as if the disease might be of infectious origin, a hypothesis which Francotte advanced in his case. In this connection it may be of interest to note that it is reported that Wallace Taylor, of Ozaka, has found a spirillum in the blood in beriberi, which can sometimes, after cultivation, reproduce the disease. We have not seen the original account of these pure cultures, however.

Francotte and Eulau also mention certain factors of importance in the diagnosis of multiple neuritis. The latter, from the case that he reports, corroborates Strümpell's statement that severe initial motor symptoms, associated with sensory disturbances, point to multiple neuritis. Severe pains and sensitiveness to pressure over the nerve-tissues, are corroborative. Trophic symptoms, like bed-sores; vaso-motor symptoms, like œdema or a rapid pulse; and secretory disturbances are not sufficient to exclude neuritis, as they were all present in Eulau's case. Francotte, in the differential diagnosis between multiple neuritis and anterior poliomyelitis, states that in the former disease the termination is much more favorable; in neuritis the loss of volitional power in the affected muscles and the loss of electrical excitability go hand in hand, while in poliomyelitis the volitional power may be quite good even with distinct reaction of degeneration; in poliomyelitis, too, there are no sensory symptoms, and definite groups of muscles functionally related are attacked by paralysis.

[Francotte's statements do not agree with the experience of others. The prognosis for an ultimate *restitutio ad integrum* of the affected muscles may be better in neuritis than in poliomyelitis, but the prognosis as regards life is a different matter. No case of death is known to have been caused by anterior poliomyelitis, but multiple neuritis, is always a grave disease, and not infrequently proves fatal. The reporter has repeatedly seen some volitional power in the muscles where faradic excitability was lost and reaction of degeneration was present, and this has been confirmed by other observers. Some sensory disturbances may be present in poliomyelitis in its initial stages. The question of differential diagnosis may be quite easy or it may be extremely difficult, and the two affections have been repeatedly confused. Marked pain, paræsthesia, distinct tenderness over the nerve-trunks, and paralysis of muscles supplied by the same nerve and not necessarily functionally related are the important diagnostic points in multiple neuritis as distinct from anterior poliomyelitis.]

ALCOHOLIC PARALYSIS.

Recent observers agree that alcoholic paralysis and alcoholic ataxia are both of peripheral origin— that the affection is one form of multiple neuritis—a term which now must be used to mean simply a pathological change resulting from many distinct affections, rather than a special morbid entity. Dreschfeld [9] and Strümpell [10] divide this alcoholic neuritis into two varieties, alcoholic paralysis and alcoholic ataxia, which many other observers have followed. Krücke [11] giving the last variety the name of "pseudo-tabes of alcoholics." Dreschfeld considers the ataxic form a milder type. The patients complain of severe pain, chiefly in the lower limbs; there is diminished sensation with some hyperæsthesia, marked tenderness over the nerve-trunks, an ataxic gait and ataxia in the hands, inability to stand with the eyes shut, and loss of patellar reflex. In Dreschfeld's cases there was little paralysis or atrophy, and merely a quantitative diminution in the electrical excitability. The paralytic variety shows an increase of the sensory symptoms, with paralysis, atrophy and loss of electrical excitability, often associated with reaction of degeneration. With this Dreschfeld calls attention to the peculiar and characteristic delirium which attends the disease. The patient answers questions rationally, but his memory is defective and he has delusions. He states that he gets up and goes to different places, describes them, and tells of the people he meets, giving full and minute details of his own and others' words and actions. In one case of the ataxic form which came to autopsy the cord was healthy but the sciatic nerve was found degenerated.

Buzzard [12] reports a number of cases of alcoholic neuritis, in some of which there were muscular contractions so severe as to require tenotomy. He thinks that in this form of neuritis the pain and hyperæsthesia are unusually severe, and that there is a much greater tendency to muscular atrophy. He has noticed mental symptoms similar to those described by Dreschfeld, and also nervous symptoms suggestive of incipient delirium tremens. As a rule, the patellar reflex is absent, but in a few cases it has been exaggerated, perhaps from an interference with the inhibitory influ-

[12] Op. cit.

ence of the cortex cerebri from alcohol. On recovery the patellar reflex returns. He lays stress on one symptom which he thinks as characteristic of alcoholic paralysis as wrist-drop is of that from lead — namely, dropped feet, and he claims that this symptom always justifies an inquiry into the patient's habits.

Schulz [13] reports a case in a hard drinker, beginning with mental confusion and followed by atrophic paralysis of all four extremities. The patient also had slight paræsthesia, but no loss of sensibility or muscular sense; pain, tenderness over the nerve-trunks, some febrile articular disturbance, loss of patellar reflex but no ataxia, retained cutaneous reflexes, involuntary passage of urine and fæces (due as he thinks to the mental impairment), diminished electrical excitability of nerves and muscles to both currents without qualitative changes, and temporary paralysis of the abducens. He believes the process to be a pure neuritis, although the brain may also be affected. Some authors have claimed that there was a formation of vacuoles in the ganglion cells of the anterior cornua, but this he thinks is produced artificially. Charcot, he says, is of the same opinion.

Hun [14] reports two cases, one of which came to autopsy, in one of which there was marked ataxia, and in the other decided atrophy. In the first case there was little atrophy, slight sensory disturbance, and little hyperæsthesia; in the second all these symptoms were pronounced, and the conduction of pain was delayed. In both there was pain, muscular weakness, reaction of degeneration or an approach to it, pain on pressure, ataxia, and a loss of patellar reflex. Both cases exhibited mental disturbance. A lesion in the brain alone could not account for all these symptoms, and a lesion in the cord would have to be very widely distributed, involving the anterior cornua and the posterior columns. This he thinks improbable, and thus, by exclusion he places the lesion in the nerves. The autopsy showed the cord normal, but there was degeneration and atrophy of the nerve-cells in the cerebral cortex, congestion of the pia, and a serous effusion into the sub-arachnoid space. The peripheral nerves were not examined. Hun concludes that drunkards are especially liable to multiple neuritis, and that alcoholic paralysis is simply multiple neuritis complicated by other symptoms of alcoholic poisoning, such as mental derangement, tremor, and ataxia,— symptoms which seem to be due to changes in the cerebral cortex.

In regard to the pathology of alcoholic neuritis, Gombault states [15] that the anatomical characteristics are very like those of Wallerian degeneration, but that, beside the degenerated fibres, others are found where the myeline sheath appears finely emulsified and composed of fatty granules. He also finds the peri-axial segmentary neuritis mentioned above, which he thinks is especially common in the alcoholic form.

Œttinger, in a recent monograph,[16] gives an extensive account of the whole subject. The paralysis is never abrupt in its onset, but is preceded by mental disturbances, pains, and paræsthesia. There may also be transient œdema of the extremities. These symptoms are followed by more or less motor disturbance, weakness, paresis, and finally, perhaps paralysis. The paralysis is never complete, and voluntary power may remain to some extent after the faradic excitability of the muscles has vanished. He claims that the muscles of the face and the sympathetic nerves are never involved, and that contractures are never seen — a statement which is at variance with the reports of other observers and with our own experience. Great stress is laid on the vaso-motor and trophic symptoms, redness, sweating, œdema, and "glossy skin." The ataxia is merely a complement of the paralysis, and the atrophy is secondary. He finds increase of the nuclei in the nerves, tumefaction of the protoplasm, and a breaking of the myeline into lumps. Later on, the axis cylinder breaks up, and the nerve is finally reduced to its sheath. Pulmonary tuberculosis was a frequent complication.

The diagnosis is often very difficult. Strümpell lays stress on the fact that the Argyll-Robertson pupil, the girdle sensation, and vesical disturbances seem to be absent, as a rule, in the ataxic form — pseudo-tabes — while they may be present in genuine tabes. Atrophic paralysis is evidence against true tabes. Buzzard also calls attention to the electrical changes in neuritis, and the fact that the patellar reflex may return. The exclusion of anterior poliomyelitis may be still more difficult. Schulz bases his diagnosis on the multiple distribution of the morbid process, the marked atrophic paralysis and diminution of electrical excitability, the slight sensory disturbances, the loss of patellar reflex, the tenderness and the pains, and the fact that the electrical excitability and the patellar reflex returned, and the patient recovered after leaving off the alcohol. Buzzard states that three points should be borne in mind: in anterior poliomyelitis, the first stage of increasing intensity of symptoms is much shorter; muscles functionally related are simultaneously affected, while in neuritis the muscles attacked are those in the distribution of the nerve-trunks; in neuritis, there is usually pain and tenderness on pressure over the nerves — symptoms which are generally absent in poliomyelitis.

Schulz gives the report of eleven cases, of which five died, four recovered, and two improved. In those that died the cord was normal, and the nerves degenerated in every case. Œttinger and Buzzard also claim that the prognosis is always grave, especially if the patient returns to his old habits.

This subject cannot be dismissed without a reference to the connection between alcoholic paralysis and amblyopia *ex abusu* described by Standish, and already published [17] in this JOURNAL.

— A Western contemporary says that a young man went to the department of diseases of women in the Chicago Polyclinic and said that he had a disease of a woman and wanted to be treated.

— The *British Medical Journal* tells of a scybalum so large that in order to extract it, it was necessary to give the patient chloroform and apply Simpson's short forceps. The patient, a woman, suffered from delusions which appeared to be due directly to the intestinal accumulations.

Clinical Memorandum.

URINARY INCONTINENCE OF CHILDREN TREATED BY ANODYNES PER RECTUM.

BY EDWARD T. WILLIAMS, M.D., OF ROXBURY.

It is safe to say that the modes of treatment usually recommended for this distressing infirmity are frequently ineffective and disappointing. A failure of my own some years ago with a child nearly related and especially dear to me, led me to cast about for some improved method. For the past year or two I have been trying, with complete success thus far, the use of anodynes by the rectum, in the form of injections and suppositories of morphine, belladonna, or atropine. I have now cured about six cases by this means, besides temporarily relieving many more who have passed out of sight during treatment, so that I cannot positively state the final results. I have no doubt, though, that a portion of these have been cured. Some of them were patients of the Sea Shore Home, where the length of stay averages less than a fortnight — too short a time to effect a permanent cure in any case. One of my cases, which I will describe presently in detail, had been a constant sufferer for ten years. The treatment occupied a year, off and on. She is now entirely well.

I find that morphine alone relieves for the time being, but does not cure. Belladonna and atropine are curative, when continued long enough, though I find them to be better borne in combination with a little morphine, which counteracts some of their bad effects, and enables them to be given more continuously. Furthermore, the requisite dose of belladonna is smaller when combined with morphine. When these medicines produce headache or undue nervous excitability, I use the bromides as a corrective, or suspend their administration for a time. I have found no case where they could not be borne when properly given.

As to the mode of administration, a fifteen-grain suppository of cocoa butter is most easily handled, and that which I prefer. They should contain a proper amount of extract of belladonna and morphine. For a child five years old, say, one-eighth of a grain of belladonna extract, and one-sixteenth grain of morphine; but the doses must be carefully adapted to the particular case in hand, beginning with a small dose, with a smaller relative proportion of belladonna, and increasing the latter and diminishing the morphine as toleration becomes established.

If an enema or clyster be preferred, it should consist of about a drachm of lukewarm water, with a few drops of atropia and morphine solution added, and administered with the small hard-rubber syringe (No. 2) especially designed for the purpose. The old-fashioned clyster of starch-water and laudanum is absurdly out of date. I have used nothing for years but morphine and warm water, mixed as for a subcutaneous injection, only that the water should be tepid, and not exceeding a drachm in amount. I hardly dare claim to be the originator of this self-suggestive plan, though I certainly never heard of its being done by others before I adopted it out of my own fancy years ago, since which time I have freely mentioned it in conversation and before various societies. It is certainly the simplest form of anodyne clyster.

At the Sea Shore Home, where we do things by wholesale, I have two solutions of morphine and atropia ready made. The first consists of one-sixth grain of morphine and twenty minims of water. The dose by drops therefrom is the same as that of laudanum, which makes it especially convenient for the nurses. The other is one-sixtieth grain of atropine to twenty minims of water. Reckoning one-sixtieth of a grain as an average commencing dose for an adult, the dose for a child may be graduated by drops precisely as with laudanum. For a child five years old, then, as an enema, you might give for a commencing dose from three to five drops of each solution, mixed with a teaspoonful of warm water. These doses may be differently combined or altered in any way to suit a particular case.

I mention these points because it is convenient to have both in private and hospital practice certain methods of routine, not only to save thought and labor, but to lessen the chances of mistake.

I will conclude by recounting a single case as an illustration of this mode of treatment. A bright and charmingly pretty girl of fourteen came under my care for this disease July 9th, 1883. Had been subject to it for years, in fact nearly all her life. Was of a peculiarly sensitive nervous temperament, and subject to convulsions in infancy and early childhood, for which I had myself attended her. Was just beginning to menstruate. The urinary trouble had become a great source of mortification to her, and her shyness about it was so great that she could not be brought to talk with me on the subject, so that all communication had to pass through the mother, a thing I should hardly have put up with if it had not been one of my particular families. This being my first case (of rectal treatment) I began with morphine alone, one-sixth of a grain nightly, in suppository. Failing to produce full relief I doubled the strength, making one-third of a grain, when she went nearly a month without once wetting the bed. On stopping the suppository the trouble quickly returned. Recommenced the one-third grain suppository on September 14th, with full relief of the incontinence as before, but the patient, who was attending school all the time, began to get "fidgety" and nervous from the effects of the morphine, so that I was compelled to give small doses of bromide of potassium daily. This relieved the nervous symptoms entirely. I then began to taper-off on the morphine, giving a suppository every second or third night instead of every night, or occasionally halving the suppository. On this treatment she began to wet more frequently, and I became satisfied that morphine alone would not cure her. October 29th I prescribed a suppository containing one-sixth grain of morphine and one-fourth grain extract of belladonna. On December 10th I made it one-eighth grain morphine and one-half grain extract of belladonna. Both these answered perfectly, and in six weeks she was practically cured. In the succeeding six months she did not wet more than six times, but each time was carefully followed by the use of the belladonna suppository for one week to prevent a relapse. For two years now, since the summer of 1884, she has been perfectly well and improved greatly in general health.

I might report other cases far more rapidly cured. I select the above on account of its long standing, and, since I was obliged to proceed somewhat tentatively, as showing very well the comparative action of morphine and belladonna. The latter I have never given

without some morphine, believing they act better in combination, as they do when given by the mouth.

From my present experience I regard the rectal treatment as superior to all others in this disease.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY. SUFFOLK DISTRICT. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

ALBERT N. BLODGETT, M.D., SECRETARY.

JUNE 8, 1886. The meeting was opened at eight o'clock, by the Chairman, DR. F. I. KNIGHT. The records of the meeting at which the subject of

MILITARY DRILL AND PHYSICAL CULTURE

was first discussed, were read and approved.

PROF. D. A. SARGENT, of Harvard University, was introduced, and opened the further discussion of the same subject by a paper [1] in which the defects of the present mode of physical instruction were pointed out, detailing the reasons why military drill as a means of exercise is inadequate in character, and injurious in effect. The claims established by Prof. Sargent against the efficacy of the drill were illustrated by means of a student of Harvard University, who having the clothing removed from the upper part of his body, performed the evolutions of the manual of arms before the audience, with the chest and arms uncovered, so that the muscular movements attending these exercises were plainly visible to those in the hall.

Prof. Sargent then illustrated other forms of physical exercise by means of the nude subject, and showed the relative efficiency of Indian clubs, wands and pulley-weights. Prof. Roberts, the Superintendent of the Boston Young Men's Christian Association Gymnasium, then gave a nude exhibition drill in dumbbells, which elicited generous applause. This drill is one of the most important features of the class-exercise at that Institution, and is considered very important in aiding the symmetrical development of the body. One of the most objectionable features of the military drill is found in the fact that the movements are essentially one-sided, and their effect upon the body is to make it unsymmetrical, often inducing a marked drooping of the shoulder of the right side, and sometimes doubtless causing curvature of the spine. The curvature once produced, it is quite easy to perpetuate it. Ladies often acquire lateral curvature from the habit of carrying the train always in one hand, and thus producing a tendency to curvature, which other forms of exercise, such as horseback riding, etc., may perpetuate.

The setting-up drill was then demonstrated, and the good features of this exercise pointed out. The fact was strongly brought out that physical training needs the careful supervision of an educated instructor, to direct the exercises to the needs of the particular individual, and thus prevent the harm which may, and no doubt does arise from the unintelligent and injudicious use of what in well-directed channels is a most important adjunct to physical health.

PROF. HITCHCOCK, of Amherst College, was introduced, and said that he had but few remarks to add to what had been said.

The subject of physical training is a broad one, and concerns all the pupils in all our schools. It is not the introduction of all forms of training that is needed, but of chosen and carefully adapted forms of exercise for the conditions arising in the individuals before us. A library has been said to be not a collection of books, but a selection of books; and so the features of physical training may be very different in relation to the special requirements of each person.

The average college boy is a rather hard animal to drive, and is apt to kick over the traces. He must be catered to in the laying out of irksome duties, so as to get as much pleasure with the labor as possible. Military drill is objectionable on account of the character of the exercise, and on account of the discipline. If we desire to make a mere automaton of a boy, to deprive him of his thinking faculties, to make him dependent on orders and directions of others, then military drill is a good thing. Is this system the right one? I think not. Every boy is examined in all the branches of his curriculum, and his progress is in accordance to carefully prescribed directions. The same should be true in relation to physical training as is true in relation to mental or moral training. Boys should not be turned into a gymnasium as calves are turned into a pasture, but should be carefully overlooked and guided, in order that the very means for their physical benefit may not become an agent of harm, or positive danger.

GEN. HOBART MOORE, Instructor in Military Drill in the public schools of Boston, said that he had been much interested in the exhibition of the drill, and not less amused. He would not be surprised to find curvature of the spine, or any other deformity resulting from the exercise of the drill as this was done before the audience. In actual practice, however, the evils represented and charged to the drill, are not observed. The statement has been made that the drill is confined to one side of the body. This is not so. The drill is made to embrace movements in exercise of both sides of the body, and the result of its employment is not asymmetrical development of the body of the boy. In addition to this, the actual practice of the drill is preceded by exercise in the "setting-up drill;" so that every possible source of defective or restricted exercise is removed.

Gen. Moore stated that he had pupils in Harvard and in other schools, and was constantly receiving most encouraging reports from them as to the influence of the drill-movements, and their relation to the bodily health and well-being of the pupils. In all the schools where the drill has been introduced, the boys are anxious to join, and often it is necessary to refuse permission to ambitious youths on account either of the small size of the applicants, or on account of their years. The parents of boys often come to the school to beg permission for their boys to join in the drill. An experience of twenty-five years in the practical teaching of the drill has convinced him that it is not only not harmful, but is of positive advantage both in relation to the physical development of the boy's constitution, and also in relation to the training of the mental and moral nature.

If this were not so, the drill would long ago have been discarded from the curriculum of our public schools. The striking rarity of accidents in the exercises of the

[1] See page 245 of the Journal.

drill is another feature to recommend it. In relation to the boys who are excused from drill, the fact is that more boys are exempted from drill on account of the effects produced by the abuse of gymnastics, than from all other causes put together. The boys themselves always want to drill. Objection to the drill does not come from those interested in it, the boys themselves, but from those who have no actual information on the subject, who are striving to upset an institution which the experience of years has found to be productive of great good, and to be free from serious harm.

Prof. Sargent stated that some of the criticisms of Gen. Moore seemed to him unnecessarily harsh, and quite unjust, as far as they related to the illustration of military drill as illustrated by the young man who had performed it before the audience. The gentleman is the son of an officer in the United States Army and has been familiar with military tactics for many years. He has a brother at West Point. He has been himself for some years under practice in the exercise of the drill and is one of Gen. Moore's own pupils.

Prof. E. M. Hartwell, of Johns Hopkins University, was introduced by the Chairman. His remarks are given in full on page 249 of the Journal.

Dr. J. P. Reynolds said that he was at one time in Frankfort, and had observed the enthusiasm with which physical culture is there carried out. It is strange that in a city one-fifth the size of Boston, so much can be done and is done, and in our own city we have nothing. The experience of seventy years in Prussia, should teach us something. We have retreated a long way toward barbarism, by our apathy in regard to the physical welfare of our children, and by neglecting them, we lay the foundation for lives of feebleness and incapacity. Nobody who has observed the people of Germany can have failed to notice how much stronger and more robust the population as a rule is in that country, than is the fact here. We are as a nation becoming effeminate and weak. The lessons of other countries are without influence upon our dulled faculties, and we have to look forward to an increased deterioration in the stock of health and vitality as the logical result of our stupidity. In Germany, even the son of the Emperor was not spared the entire *régime* of the course for physical training laid down for the preparation of the recruits for the regular army. Every man must perform this duty to his physical system, before he is considered capable of attempting the discharge of his duties toward his country. At the present time, there is such a degree of apathy among our people, that we might as well have hoped to legislate slavery out of existence, as to awaken in the minds of our citizens a proper regard for the benefits or the necessity of physical culture. Some years ago, when Dr. Reynolds was a member of the School Board, this same Dr. Hartwell was a teacher in the Latin School. In the intervals between sessions Dr. Hartwell engaged some of the pupils in gymnastic exercises, to their great delight and personal benefit. Some of our wise committee objected to this, and stated that a teacher was not employed to *play* with the pupils, and the unfortunate result was that Dr. Hartwell was legislated *out*, and there has been no proper physical exercise in the schools of Boston from that day to this.

It is not easy to speak calmly of such an abuse as this is toward all the pupils of our schools. It is hard to repress the indignation which one feels at the exhibition of such a degree of narrowness and ignorance on such an important subject, one which has to do with the health and happiness of every pupil in the public schools, of every father and mother, every family among us, and indirectly with the well-being of those on whom the burdens and responsibilities of our public and private welfare must soon rest.

Dr. D. F. Lincoln said that one important point had not been touched upon in the course of the present argument, and that is the fact that the girls need careful physical training as much as the boys, and that they have even less opportunity for exercise than have their more fortunate brothers. The people are not doing their whole duty by their children until they have given them the advantages of physical culture commensurate with their mental development.

Dr. C. F. Withington, in closing the debate, spoke of the lateness of the hour, and said that he would not prolong the discussion, although there was much to be said. He observed that the exercises of this meeting had demonstrated that the simplest of apparatus could be made serviceable for a very comprehensive system of physical culture, and vastly improve upon the form of exercises now in vogue. There could be no question that the drill leaves much to be desired as a means of physical development, which could be supplied by the simpler and less expensive form of exercises connected with the courses of physical culture as shown at this meeting.

When our school authorities have attended to the first requirements for physical culture of the whole body of pupils, male and female, then if there is any time or any money to spare let them think of supplementing the function of the State in the maintenance of a militia.

Dr. Reynolds said that he hoped that this meeting would not adjourn without some expression of its feeling of indebtedness to those gentlemen, not members of the Section, who had contributed so greatly to the intelligent discussion of this important subject, and moved a vote of thanks of the Section be extended to them for their presence and co-operation on this occasion.

The motion of Dr. Reynolds was put by the Chairman, and unanimously carried.

Adjourned at 10.40 o'clock.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.[1]

CLINICAL NOTES ON SCABIES.[2]

by Dr. F. B. Greenough, of Boston.

DISCUSSION.

Dr. A. R. Robinson, of New York. In some cases where there was difficulty in the diagnosis, I have reached a positive conclusion by opening a vesicle and examining its contents under the microscope, and finding the young acari or the fæces.

Dr. L. N. Denslow, of St. Paul. I have had a number of cases in which no burrows could be found, but under treatment suitable for scabies, they have recovered. The treatment used has been thorough scrubbing from head to foot, followed by the application of sulphur ointment. In regard to the complaint

[1] Continued from page 238.
[2] Reserved for publication in this Journal.

known as prairie itch, I should from my experience say that it was nothing more than scabies.

DR. E. B. BRONSON, of New York. I agree with the author of the paper as to the frequent absence of the cuniculi. In many cases I have depended largely upon the elongated character of the efflorescence in making the diagnosis. For three months, I treated all cases of scabies with napthol, using a fifty per cent. preparation rubbing the body thoroughly with this once. This has produced a satisfactory result.

DR. S. SHERWELL, of Brooklyn. I have recently seen an increased number of cases of scabies and a large proportion of the cases has been among Scandinavians. I thought that this might be due to want of thoroughness in the cleaning of the ships in which the emigrants are brought to this country. As a prophylactic, I always direct the patient to sprinkle on the sheet of the bed a teaspoonful of the dry sulphur. This acts as a disinfectant and is unpleasant to the acarus.

CLINICAL OBSERVATIONS REGARDING THE VALUE OF RESORCIN, ICTHYOL AND LANOLIN IN CUTANEOUS DISEASES,

by DR. H. W. STELWAGON, of Philadelphia.

Resorcin in eczema, is rarely of benefit, but possesses some power over the itching. For this purpose a six per cent. ointment is useful. In greater strength it is irritating. In tinea sycosis it has proven of some value in ten to twenty per cent. strength. In tinea tonsurans, it is inferior to the remedies usually employed. In one case of leg ulcer, healing took place under its use. In a second case, no effect was produced. In seborrhœa and alopecia dependent upon this disease, a lotion consisting of a drachm of resorcin, one or two drachms of castor-oil, five minims of peruvian balsam, and four ounces of alcohol was of value. In tinea versicolor, it was found less useful than a solution of hypophosphite of sodium. In psoriasis and in one case of lupus erythematosus, the result was negative. In one case of superficial epithelioma, a fifty per cent. ointment produced a good result. In a second case, a fair result was obtained, and in a third the result was negative. In a case of favus, a twenty-five per cent. ointment used two months produced no decided effect.

Icthyol. In a small proportion of cases of rosacea and acne vulgaris a ten to twenty per cent. preparation was found beneficial. In eczema it was valueless and usually irritating. In furunculus it acted with good results in three cases, when applied as a twenty per cent. plaster. In the fourth case it had no effect. It was of service in psoriasis and also in a case of lupus erythematosus. In favus, it was used without effect.

Lanolin. In some cases as an ointment base this is superior to the ordinary fats in use. Where a simple protective action is desired, it is inferior to vaseline, cold-cream or lard. In chronic cases, where there is infiltration and a degree of penetration is the object, lanolin is especially valuable. The writer stated that according to Liebreich, a *lanolinum purissimum* was now manufactured, in which the cholestrin ethers were absent. The main disadvantage of lanolin as now manufactured from sheep's wool, is its strong sheepy odor. In a few acute and sub-acute cases of eczema lanolin for some reason proved irritating. As a rule, however, it is bland and unirritating.

THURSDAY.— SECOND DAY.— MORNING SESSION.

The first paper was entitled:

TROPHONEUROSIS OF THE SKIN CAUSED BY INJURY OF THE MEDIAN NERVE,

by DR. G. H. TILDEN, of Boston.

E. F., fifty-five years of age, was wounded in the wrist by a circular saw in November, four months before coming under observation. The wound was parallel with the limb. It was sewed up and healed in about ten days. Three or four days after the infliction of the injury, there was loss of the tactile sense and a feeling of numbness in the last two phalanges of the fore and middle fingers. This has continued and steadily increased. There was at first a slight feeling of numbness in the thumb, but this gradually diminished until it disappeared. Three weeks after the accident a bulla appeared upon the terminal phalanx of the middle finger. Similar lesions have developed from time to time upon the last two phalanges of the fore and middle fingers. The bullæ appeared every two or three weeks and were unaccompanied by any subjective sensation. These leave superficial excoriations which heal in the course of ten days. The skin over the affected phalanges is of a white color and of glossy texture. The growth of the nails is unaffected. There was entire loss of sensation in the skin covering the affected phalanges. The right hand is capable of exerting only one-half the power of the left. The first and second interossei muscles exhibited the reactions of degenerations.

Six weeks treatment with the faradic current caused decided improvement in all the symptoms. During this period only one bulla formed. He then stopped treatment and returned to work. Three weeks later, all the former symptoms suddenly returned. It was proposed to the patient that an incision be made over the seat of injury with the view of determining the exact condition and if possible remedying it. The patient has not since been seen.

Whether the trophic nerves exist as individual and special nerve-fibres or whether the motor and sensory nerve-fibres are the ones by which the nutrition of the tissues is governed, is unknown. The latter view was considered by the author as the most rational. Injury or disease of the motor or sensory nerves as well as disease of the ganglia and central nervous system, may disturb not only motor power and sensation, but also the nutrition of the tissues. That it always does so is by no means the case, but why trophic changes should take place in one instance and not in another is not clear. A number of cases have been reported showing that such changes are more apt to follow partial injury of a nerve than complete section. The changes commonly seen in these cases are the so-called glossy skin and vesicular and bullous eruptions followed by superficial excoriation. The treatment of these cases consists in the use of electricity and the application of blisters over the seat of injury. A last resource is to cut down upon the affected nerve and endeavor to relieve any constriction or pressure which may be found. If no such condition is detected, resection of a portion of the nerve might be advisable, since complete section is not apt to be followed by spontaneous trophic changes and since it has been found by some observers that resection of a portion of the affected nerve is sometimes followed by the arrest of the trophic changes.

NATIVE PLANTS INJURIOUS TO THE SKIN,

by Dr. James C. White, of Boston.

The object of the paper was to show that the number of plants growing native and cultivated in the United States, which are capable of exciting some degree of dermatitis by contact is much larger than is generally supposed and that cases of such inflammation of the skin not infrequently occur without being understood, because the patient has not been exposed to the two or three plants which alone are considered to be poisonous. He enumerated over fifty species which have irritating properties when brought in contact with the skin. With reference to rhus poisoning, the speaker said that the rhus toxicodendron was comparatively inoccuous, while the rhus venenata was the most poisonous species of this plant. The treatment is the ordinary treatment of dermatitis. There is no specific for this form of dermatitis.

The next paper was entitled:

NOTES ON DRUGS,

by Dr. H. G. Piffard, of New York, in which he referred briefly to several recently introduced preparations.

A FEW ADDITIONAL NOTES ON PSORIASIS,[3]

by Dr. F. B. Greenough, of Boston.

CHONDROMA OF THE UPPER LIP,

by Dr. A. R. Robinson, of New York.

The tumor occupied the right side of the upper lip of a man thirty-six years of age. It had been growing for two years and was one inch in length by three-fourths of an inch in diameter. It was egg-shaped, the broad end having its seat in the sub-mucous tissue among the mucous glands. The mucous and cutaneous structures were freely movable over the tumor, which was sharply limited, somewhat encapsuled and nourished by a small artery entering at the base. Microscopical examination showed the tumor to consist of embryonic, gland, and connective tissue. The gland tissue was formed of hypertrophied mucus glands and new gland tissue. The amount of new gland tissue could not be correctly estimated, because much that resembled gland tissue, represented an early stage in the process of cartilage tissue formation. The connective tissue was myxomatous, fibrous and cartilaginous. The myxomatous was present principally at the periphery and did not represent œdematous fibrous tissue. Fibrous connective tissue was present chiefly between the islands of cartilage. The bundles were small and the fibrils very fine and often rather indistinct in outline. There were several islands of cartilage, the largest being in the central part of the tumor. All varieties of normal cartilage were present, viz.: hyaline, fibrous and reticular and also the variety met with in the heads of cephalopods, namely, cartilage with ramifying or branched cells. (*Chondromes à cellules ramifies.*)

The cells showed great diversity of forms and sizes. The body of the branched cells presented a great variety of form. Some were surrounded with a capsule, but in the majority of cases this was absent, or only faintly indicated. In some places the islands of cartilage had joined each other but usually they were separated by the other constituent tissues.

The affection was considered to be very rare. It has been described by Paget, under the name of labial glandular tumors.

KERATOSIS FOLLICULARIS, ASSOCIATED WITH FISSURING OF THE TONGUE AND LEUKOPLAKIA BUCCALIS,

by Dr. P. A. Morrow, of New York.

The patient, C. C., a sailor, aged twenty-one years, came under observation in December, 1885. Five years previously, soon after beginning his sea-faring life, he noticed a number of blackish points upon the back of the hands, some of which he squeezed out. Soon afterwards these appeared upon other parts of the body. They improved when he was on land, but were aggravated when he was at sea. The entire surface of the body with the exception of the face, palms and soles was found to be the seat of the follicular disorder. The ducts of the sebaceous glands were occupied by comedo-like bodies projecting sometimes one-fourth to one-half an inch above the surface. From many of the follicles, small white hairs protruded. The comedos when pressed out were hard and dry. The hard portion of the comedo was continuous with an adhesive substance dipping deeply into the follicle. There was no evidence of irritative or supurative action. They were not accompanied with itching.

The tongue was large and rough to the touch, the surface was deeply fissured, the fissures extending to the sub-mucous tissue. The buccal mucous membrane presented a bluish-white appearance, thickened and raised in places forming distinct plaques, which were superficially fissured. The patient stated that the tongue had been white and a little sore ever since he could remember. The absence of irritation or marked sensitiveness of the fissured organ was quite noticeable. Examination seemed to exclude the possibility of a syphilitic origin. The speaker referred to other cases which had been reported. He objected to the term ichthyosis since that suggests a disease of a different nature. He selected the term keratosis follicularis as more correctly expressing the pathological condition present as well as indicating the anatomical seat of the disorder. Drawings representing the microscopical appearances of the lesions was presented.

While in the hospital the patient improved decidedly under the use of local application of linseed oil. But within a short time of the discontinuance of the treatment, the condition became as marked as before treatment was employed.

EVENING SESSION.

A CLINICAL STUDY OF SCLERODERMA,

by J. E. Graham, M.D., of Toronto, Canada.

Dr. Graham first related the histories of two cases of this rare disease, one of which occurred in the practice of Dr. Smith, of Seaport, Ont., and the other was referred to him by Dr. Jenner, of Pictou. The first patient, Mrs. R., forty-seven years of age, had previously suffered from rheumatism. The hardening of the skin began in March, 1882, and was first noticed over the back of the neck. It gradually spread so that in about ten weeks, the integument over the greater part of the body was affected. The movements of the limbs as well as those of respiration were impeded. The internal treatment adopted was liquor ferri iodidi and liquor arsenitis. A Faradic bath over the surface of the skin was used. In six weeks the skin began to grow softer, and in ten months the patient was quite well. There has been no return of the difficulty.

The second patient, Mr. H., age thirty-seven, came under observation in May, 1886. There was a history of hereditary rheumatism. The disease had commenced some months previously. The first symptoms were stiffness of the limbs with œdema of the lower extremities. Then hardening of the skin over the hips was noticed; this gradually spread and was accompanied with pigmentation. He was given with some benefit potassium iodide at first, and latterly salicylate of sodium.

In his remarks in connection with the disease, the speaker referred to the following points; (1) That the disease is found principally in temperate climates and occurs in seasons when there are sudden changes in the weather. (2) That it is more closely related to rheumatism than has been supposed. (3) That although morphœa has in all probability a similar pathological origin to scleroderma, yet the clinical distinctions are so marked, that at present it is expedient to treat it under a different name.

DR. L. N. DENSLOW, of St. Paul. In one case of scleroderma in which there were two large plaques on each pectoral region, benefit has followed the daily use of the constant current.

CARCINOMA CUTIS,

by LE GRAND N. DENSLOW, M.D., of St. Paul.

The patient, aged forty-nine years, had been an invalid for several years. He had had a severe right pleurisy and presented the physical signs of absence of the right lung. The skin of the right chest from the second to the seventh rib and from the posterior border of the axilla to the median line was covered with a nodular new growth, which presented no ulceration. Around the nipple the nodular mass for an area of six square inches reached a thickness of one inch. The older portions of the growth were covered with thickened epidermis with thick brown scales. There was slight enlargement of the axillary glands. The different nodules were not movable beneath the skin, but the whole mass was free from the fascia. The mass was not painful on pressure but was the seat of occasional neuralgic pains. The duration of the growth was seven months. The patient died four months after coming under observation.

The autopsy showed obliteration of the right lung. The left lung presented many small solid nodules. In the mesentery there was a nodule one and one-half inches long by one-half inch in diameter. The microscopic examination of these masses showed that in them all connective tissue preponderated. The growth on the skin occupied the papillæ and the deeper portions of the corium.

DR. I. E. ATKINSON, of Baltimore. This case suggests what has been termed lenticular cancer in which the growth sometimes becomes perfectly continuous. These cases are exceedingly malignant. In a case of my own which presented appearances similar to that of Dr. Denslow's case, the disease ran its course in two or three months. These cases are so malignant that it would seem that no operative procedure is justifiable.

DR. R. W. TAYLOR, of New York. I might allude to two cases which were for a time looked upon as cases of cancer of the nipple, both in men. They eventually turned out to be cases of hard chancre, but in one case the induration was so great that carcinoma was strongly suspected.

(To be continued.)

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 16, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

PHYSICAL TRAINING OF AMERICAN YOUTH.

THE importance in any educational scheme of attention to the needs of the body is not a discovery of those who are prominent at the present time in the matter of physical training, however much these persons have contributed towards the development of a rational plan for securing this end. Dr. Benjamin Rush, of Philadelphia, one of the signers of the Declaration of Independence, and one of the fathers of American medicine dwelt with great emphasis in his published writings on the need of suitable bodily exercise for students, recommending that "the amusements of our youth shall consist of such exercises as will be most subservient to their future employments in life." Dr. Wheelock, the first president of Dartmouth College, recommended the students of that institution "to the practice of some manual arts or cultivation of gardens or other lands, at the proper hours of leisure and intermission from study and vacancies." Farm schools, in accordance with these ideas, were established in some of the States in the early part of this century. At the foundation of Amherst College in 1821, a large tract of land was secured in which charity students might have a quarter or a half acre to cultivate as they might desire. Much of the work of laying out the grounds at that college was done, we are told, as a means of exercise by the officers and students; and the expressions "chip-day," "mountain-day" and "gravel-day" indicate an established custom at Williams College, when these holidays were granted by the faculty for the purpose of "fostering in the students the habits of physical labor and exercise so essential to vigorous mental exertion."

The requirements still in vogue in some of our seminaries for a certain amount of daily manual labor from each student, are doubtless the outcome of the ideas just referred to, although little can be said for the hygienic value of most of such work. Certain kinds of manual labor, which can be performed out-of-doors, can doubtless be made to contribute to the bodily well-being. Wood-chopping, whether done by a Lincoln in the days of his youth, or a Gladstone in the years of his maturity, may prove a valuable exercise. But in the

present conditions of life, it is safe to say there are few students in school or college who are so situated as to obtain from manual labor alone proper and adequate exercise. In saying this, we would not derogate from the value, on other grounds, of industrial training, or from the commendableness, for reasons of economy, of students paying their way, so far as possible, by manual labor.

Among the various "Circulars of Information" that have been issued from time to time by the National Bureau of Education, under the auspices of the Department of the Interior, few, we think, have been of greater practical value than one which has appeared during the past summer, prepared by Prof. E. M. Hartwell, of Baltimore, who is in charge of the department of physical training in the Johns Hopkins University. The work, which comprises a pamphlet of some one hundred and seventy-five pages, contains a pretty full report on the present status of physical training in American colleges and universities.

The first gymnasium in this country seems, according to this pamphlet, to have been that established in 1823 by Dr. Beck, himself a pupil of Jahn, at the famous Round Hill School at Northampton, Mass. This was followed in quick succession by similar institutions at Harvard, Yale, and Amherst Colleges, while in 1825, Dr. John Collins Warren, of Boston, became the first president of the Tremont Gymnasium, and endeavored to secure the services as instructor therein of Professor Jahn, the "father of the Turners." In this he was unsuccessful, but he was able to induce Dr. Lieber, a man famous in law, as well as in gymnastics, to take charge of the enterprise for a time.

The "new gymnastics," so far as the colleges were concerned, began with Amherst College, to which President Eliot has said: "the colleges of the country are indebted for a demonstration of the proper mode of organizing the department of physical training." The doctrine which forms the basis of this movement is that the best physical training will not aim to make athletes or acrobats, or to develop big muscles, but simply to secure the best functional use, and hence the highest health of the various parts of the body.

The list of colleges and institutions for secondary instruction which have built gymnasia since 1860 is given by Dr. Hartwell, with the respective expenses of construction, and in many cases, with sketches and plans of the buildings. This list comprises thirty-three buildings, and the cost aggregates $600,000. In addition to this, some $150,000 has been expended by schools and colleges for gymnasia which do not occupy an entire building; and a considerable number of "projected" gymnasia are mentioned, most of which, with a few others not mentioned in the book, have since been completed. We note with especial interest the establishment of gymnasia for the use of women at the following colleges: Vassar, Smith, Cornell and Wellesley, and Bryn Mawr. The last mentioned college has a remarkably attractive and well-planned building, completed at a cost of $18,000, with a main hall 80 × 30 feet, with running track, a room for special apparatus, bowling alleys, abundant bathing facilities, all arranged with reference to maintaining the strictest privacy, so that students may take their exercise without the least fear of intrusion.

The progress made in the matter of buildings and appliances for physical culture, though it leaves much to be desired, particularly in our public and preparatory schools, has been more rapid than that in the provision of proper instruction in the use of the appliances. Until very recently these responsible positions have been filled by men of the grade of broken-down boxers, superannuated drill-sergeants, acrobats and other "sporting" characters. But of late a corps of trained teachers of bodily culture has begun to be formed, from whose work we may hope to see good fruits.

May there not soon be, if there is not already, an opportunity for a new specialty in medicine in which regularly educated physicians shall undertake this eminently practical branch of "preventive medicine," making it their object to bring the bodies of the youth up to a standard of physical perfection, coincidentally with the training of their other powers?

The work of the *turnvereine*, described so graphically in Dr. Hartwell's pamphlet, as well as in the article by the same gentleman on another page of this Journal, has, we have no doubt, been somewhat discredited in the minds of American observers by the various heresies, political, religious and socialistic which have developed in that organization since it first began to be a thorn in the side of German absolutism. But the excellence of the physical results brought about by its means is indisputable. And our educational authorities might do much worse than to employ, at least for a time, until the regular teachers can be instructed as in Germany in the work of training the bodies of their scholars, some of those who have been educated under the auspices of this great organization.

It is quite evident from the facts presented in the pamphlet referred to, that much may with profit be learned from the system which during the last fifty years has occupied so important a place in the German volk-, student and army life. That the foremost military nation of the globe should place so little value on military tactics in comparison with gymnastic exercise for the purpose of developing the bodies of its soldiers as is shown by the statements taken by Dr. Hartwell from the latest *Vorschriften über das Turnen der Infanterie*, is a most significant fact, and suggests emphatically the deficiencies of that educational system in our country which has nothing better to offer our children physically than to allow a few of them to play at soldiers.

THE PHYSIOLOGICAL EFFECTS OF FEAR.

The recent earthquake in South Carolina, whereby many lives were lost, and a considerable part of the city of Charleston laid in ruins, has furnished a signal demonstration of the effects of terror on communities.

A large portion of the population, even those whose tenements were spared, were panic-stricken and abandoned their homes, spending their days and nights in the open air, some in tents, some with nothing to shelter them, and now that the alarm is subsiding and confidence is being restored, they are gradually returning within the precincts of the city. Eye-witnesses have described the terror as something unprecedented: especially among the negro population, who spent their time in wailing and supplication: many forgot to eat, and few were able to sleep. Many women became hysterical, and some men lost their reason; among pregnant females miscarriages were numerous.

The emotion of fear takes its origin in that strongest primordial instinct, the instinct of self-preservation. Conspicuous in its manifestations in the lower animals and among savages, where it is the parent of every superstition, not even the enlightened philosopher can wholly divest himself of the thraldom of this imperious power, especially during such convulsions of Nature as that above referred to, when men's confidence in the stability of the world under their feet is so rudely destroyed. A life-long experience added to the experiences of countless ancestral generations has led the generality of mankind to trust the seeming security of the earth's stability, and the revulsion of feeling and the maddening terror which they realize when this seems to fail them, is something that no words can describe.

Fear is essentially subjective, hence the lowest animals whose actions are judged to be purely reflex would seem to be devoid of it. Being the effective subjective expression of the instinct of self-preservation, it is, within certain limits, a healthful sentiment without which life would not long be possible, especially to wild animals. First called into being by the experience of pain, this emotion is early awakened in all animals by the ideal representation of pain, such ideal representation with the corresponding feeling being also, as Spencer has shown, inherited. Rising within the sphere of consciousness, and hence being presumably cerebral, this emotion, (or perhaps, to speak more correctly, the cause which produces it), instantly excites diffusive discharges of nervous energy, which tend to concentrate themselves on the nervo-muscular apparatus by which escape from danger is effected. If the latter be possible the fear shows itself the most powerful stimulus to self-protective action; witness the achievements of swimmers, swimming "for their dear life," or the speed and endurance of routed soldiers fleeing before a victorious foe.

But if fear under some circumstances is a healthful stimulus, as when it concentrates the nervous and muscular powers on the means of escape from threatening danger; under other circumstances, as when it is vague, ill-timed, or excessive, it is an evil, paralyzing the higher cerebral and the organic functions. In fact, fear is always reckoned among the depressing passions which lessen vital action. The intense concentration of the consciousness on the subject of dread, and the forebodings associated therewith inhibit the will and the judgment, rendering sane and deliberative action impossible. Generals, under the influence of fear, have been known to fly from the field of battle when their troops were winning the day, and strong men have surrendered their possessions to the unarmed highwayman, when a little courageous resistance would have given them an easy victory. A runaway horse and a panic-stricken herd are instances of animals rendered mad by fear. Fear may be so excessive as to inhibit all movements; this has been noticed in the case of the horse. The paralyzing effect of this emotion has at some time been remarked by every one who has been called upon to address a public audience.

The cardiac innervation is disturbed by fear; the pulse and heart beatings are accelerated, and fainting may ensue. This has been attributed to sudden anæmia of the bulbus, and paralysis of the pneumogastrics. This is one of the best known effects of fear; it is the action of the heart which is connected with trepidation and nervous excitement. The vaso-motor centre is weakened, and the vascular sluice-gates of the viscera are opened, hence congestions occur; fear has even caused jaundice and diabetes. The reproductive function is paralyzed; sometimes the sphincters lose their power of control. Digestion is interrupted; in fact, all healthy innervation is diverted from the digestive organs; the salivary, gastric and other secretions are arrested. Hence the nausea, vomiting, and diarrhœa, which often accompany emotions of terror. The peripheral coldness, the trembling, the intense muscular weakness which result from the circulatory and nervous disturbances, are well known. In fact, under the influence of fear, that equilibrium in the distribution of nerve force which is so necessary to the harmonious working of all the functions of the organism is broken.

The operation of this sentiment in civilized communities is still more influential than one would, at first thought, suppose; sickness may at any time cause a panic in certain circles; there are patients too, who, with trifling ailments, are all their life long under bondage to fear. One of the offices of the physician who realizes how states of pain depress all the vital processes, and how intimately and indissolubly the physical expression of the emotion is bound up with the subjective experience thereof, is to lift his patients out of this bondage of fear, and promote courage, firmness and all the elevating passions instead. "The susceptibility to terror," says Bain, "is a weakness and an evil, while the consideration of the means of avoiding or subduing it is of the greatest practical moment."

THE OVERCHARGE FOR PATENT MEDICINES.

THE very excessive prices over and above their actual cost often charged by manufacturers of patent or proprietary medicine for their goods have caused the authorities in several of the continental countries of

Europe to enforce certain regulations upon them for the better protection of the people.

Thus in Germany the police cause the medicine to be analyzed, and then they publish the name of the article, that of its proprietor or manufacturer, with the usual price charged for the preparation. With this is given the actual composition of the medicine as found by the analysis, and the ordinary cost of the ingredients. In Russia and Japan none of this class of preparations are allowed to be imported by the custom authorities except such as have been found upon analysis to contain no poisonous substance.

One of the most efficient methods for discouraging the sale of these preparations is to require each retail package to have upon its label a true copy of the formula of its composition. The effect of this in most cases would be to entirely suspend all demand for the preparation. This may be fully as efficient as any prohibition could be expected to be, and thus the desired result be gained without any unjust exercise of authority. It is in short, but an instance of a thing being justly regulated out of existence when an arbitrary prohibition would not be legitimate. Would it not be well if in this country this last mode of procedure was enforced by legislation?

MEDICAL NOTES.

NEW YORK.

— Dr. John Burke, a well-known practitioner of very large experience, died at his residence on Lexington Avenue, September 9th, at the age of fifty-nine years, of pneumonia. He was a native of St. John, New Brunswick, and graduated at the New York Medical College in 1849.

— A patient has died at Bellevue Hospital, who fired seven shots into himself with a 22-calibre revolver at the Grand Union Hotel, but in whose case, owing to the prompt and skillful interference of one of the house-surgeons of the hospital, life was prolonged for two weeks, and it was even thought for a time that there was an excellent chance of recovery. Five of the wounds were serious, and two of them were especially dangerous; one of the balls being fired into the top of the head, fracturing the skull, and another into the throat, severing the larynx. For the relief of these, trephining and tracheotomy were performed at a single sitting.

— Dr. Edson, of the Health Department, has been making an investigation of the milk brought to the city over the various railroads, and has found that in some instances it was diluted with as much as forty per cent. of water. On September 10th, he made a report to the Board of Health of an inspection recently made by him of ten candy factories. At one of them he found a quantity of Venetian red, which is used to give color to low grade chocolates, and in another, some burnt umber, which is used in the coloring of Christmas toy candies. In none of the other establishments were any pigments found in use which are deleterious to health.

— Dr. Thomas Alexander McBride, one of the most talented and promising of the younger physicians of New York, died, at the age of forty, on the North German Lloyd steamship "Aller," at sea, on the 31st of August. He had been suffering for some time from Bright's disease, and had spent the summer under treatment at Carlsbad. He improved to some extent, but after reaching Southampton, on his return to America, he became quite ill. His body was buried at sea. Dr. McBride was a native of Ohio, but received his medical education at the College of Physicians and Surgeons of New York, in which city he has since resided and practised. He was at one time lecturer on symptomatology in the College of Physicians and Surgeons, and at the time of his death was a lecturer in the Yale Medical School, and attending physician to the Presbyterian Hospital in New York. He had a large consulting practice in diseases of the nervous system and of the kidneys, and was held in the highest esteem not only on account of his professional attainments, but also for his many amiable and social qualities. He was the author of many medical papers of great value, and was an honored member of the Academy of Medicine, the Neurological, the Practitioners', and other Societies.

— The first case of yellow-fever which has come to the knowledge of the sanitary authorities for over two years in the city of New York, was discovered on September 5th. The patient was twenty-three years of age, and employed as a fireman on the steamship Alvo, of the Atlas Line, which sailed from Savanilla on August 12th, and, after touching at Carthagina, Aspinwall, Leinon, and Navassa, arrived at the port of New York on August 29th. The vessel passed quarantine on a clean bill of health, and on reaching the city the crew were paid off and went ashore. The fireman, Golden, took a room at a lodging-house on West Street, and then went on a spree which lasted for several days. On September 2d, he was taken sick, but as his illness was supposed to be the result of intemperance, very little attention was paid to him. On the 4th, however, he became delirious, and was removed by the police to St. Vincent's Hospital, where the case was regarded as suspicious, and was isolated and carefully watched. On the following day the symptoms were pronounced by physicians familiar with the disease, to be unmistakably those of yellow fever, and the patient was at once removed to the Reception Hospital at the foot of East 16th Street, where he died on the 7th. The lodging-house where the man had had his quarters was thoroughly fumigated and disinfected by the sanitary officials, and every precaution taken to prevent any spread of the disease.

— A party of Sanitary Inspectors and Health Department clerks who started out on the "Franklin Edson," a propellor belonging to the Department, to

see the race between the Mayflower and Galatea on September 9th, which was spoiled by the fog, had a most uncomfortable and trying experience. On the way down to the Sandy Hook lightship the machinery got out of order, and an hour was consumed in setting things to rights. Consequently, the "Edson" got down too late to see the start, and was compelled to keep in the wake of the long line of excursion boats; so that the party did not even sight the competing yachts at any time during the race. On the return homeward they were caught in the thick fog, and at eight o'clock the darkness was inpenetrable; while the pilot whom they had taken on board at Lewis quarantine, confessed, much to their annoyance, that he did not know where he was. The engine was stopped and the boat allowed to drift; the fog-whistle in the meanwhile, being blown continuously. After drifting for several hours, the engine was started again and the boat was steered by compass. She had not been in motion very long, however, when she ran aground on a sandbar which proved to be at the entrance of Rockaway Inlet. All attempts to back her off proved futile, and she lay at the mercy of the waves which washed over her decks. Most of the party were seasick and thoroughly alarmed, and the situation was altogether most unpleasant. It was nearly three o'clock in the morning, after they had been aground over five hours, before aid reached them. The signals of distress sounded on the steam-whistle had attracted the notice of the members of the life-saving station at Rockaway beach, a mile and a half distant, and a large boat was put out to the rescue. After being landed on the beach the party were compelled to walk nearly five miles to the nearest railroad station, where they finally took a train for the city at seven A.M.

Miscellany.

LAPAROTOMY FOR GUNSHOT WOUND OF INTESTINES.

DR. W. T. BULL, of New York, has performed another successful laparotomy for gunshot wound of the abdomen. A sailor, aged twenty-five, was shot in the abdomen, August 12th, at 7.40 P.M., the ball entering two inches below and to the left of the umbilicus. He was taken to the Chambers Street Hospital. Two hours after his arrival the abdomen was opened, the wound having been first explored and found to be penetrating. There were no symptoms of any inter-abdominal injury. The pulse was 94, respiration 24, and temperature 98°. Much blood was found in the cavity, the small intestine was pierced in two places, the sigmoid flexure in one, and there was a wound of the sigmoid mesocolon, from which copious venous hæmorrhage took place. The operation lasted one hour and a half, and was well borne. It was followed by no vomiting or other bad symptoms. There was but slight pain and a moderate tympanites. The pulse ranged between 90 and 110, temperature between 99° and 100°. There was a natural movement of the bowels on the fifth day. The case continued to progress favorably and now (at the end of the third week) the wound is nearly healed and the functions of the alimentary canal have been normal for two weeks. There has been no peritonitis.

A DANGER FROM PUBLIC BATHS.

AN interesting case is recorded by Dr. Aubert, according to the *British Medical Journal*, in which blennorrhœa was communicated by means of a bath. A lady consulted him for her child, aged four years, who for some days, had had an abundant vulvar secretion. The child complained also of pain and burning in passing urine. In relating the case, the mother stated that she herself had, for some weeks, been affected with a like discharge, and her husband with an urethral discharge. According to the lady's husband, this was due to drinking turbid wine; an explanation which, as it was satisfactory to the lady, was not questioned by the medical man. A microscopic examination revealed the gonococcus in the discharge from both mother and daughter. On further inquiry, it appeared that the child, three or four days before the appearance of the discharge, had taken a bath with its mother. No other possible source of infection could be thought of. In the same family there was another child which did not have the bath, and which escaped the infection. Professor Filippi, of Florence, commenting on this case (*Lo Sperimentale*, October, 1885), relates that during the previous year, fifty-five little girls were infected with vulvitis at the public baths of Santa Lucia at Florence. Some of the children also contracted severe purulent inflammation of the eyes. The only explanation of this outbreak was, that the contagion had been deposited in the water by some woman or child already infected. Professor Filippi goes on to remark on the hygienic and medico-legal aspects of the case. It is not always possible to make sure that people making use of public baths are free from every sort of infectious disease. Unless, therefore, the supply of water be undergoing constant renewal, the water ought to be changed for each person. The forensic aspect of the case is also important. When a child, with vulvar discharge, is brought for examination on account of a supposed criminal assault, the above-mentioned mode of infection ought to be borne in mind.

Correspondence.

ENDORSING PROPRIETARY HUMBUGS.

MR. EDITOR,— I beg to enclose you a very readable circular [1] which is being widely distributed in the section of country of which Podunk is the centre. Will you kindly peruse it at your leisure? In it you will see testimonials from many great men, alleged leaders of the profession, regarding the merits of the "new quinine."

If you will read the paragraphs that I have marked you will learn much. The first novelty to me was that "the most celebrated and widely-known physician and surgeon in the United States" is Montrose A. Paller.

Another matter of great surprise is that such men as Loomis and Howe and Drake should endorse such stuff as *kaskine* and should allow their endorsement of it to be spread broadcast over the country in this way.

[1] How Discoveries are Made. Kaskine.

Now in the neighborhood of Podunk malaria prevails, as you have reason to know, and there prevails there also a strong prejudice against quinine; and when I received this flowing announcement which I enclose, bearing autograph letters and temperature-charts and other endorsements from well-known men, I bought a lot of the stuff — being an inexperienced and youthful practitioner — and promised my patients a speedy deliverance from their ills without the use of quinine. I tried it, and I proved it in a large number of cases to be just as inert as so much flour.

No one knows how many others may have been deluded by the same men that deluded me. Have we no redress, Mr. Editor? Can these alleged "leaders of the profession" deliberately thus combine with the quack-medicine venders for some occult reason and bring discredit upon honest toilers like myself? Of course *I* shall not be again deceived by these men. It has lost me my reputation in Podunk and my office is now to rent. I must move, sir, hungry as I am, into some region where I am unknown, and through no fault of my own, but my credulity.

Do you wonder that the profession in this country stands upon a low plane? It seems to me that with such alleged *leaders* the plane must always be low.

Of course if I were not young and inexperienced I would at once have had my suspicion aroused by the very incredible reading at the beginning of the circular of this inert stuff; but being young and inexperienced I overlooked that when I saw the names and titles of the men that endorsed it.

I speak for many beside myself, sir, and I venture to hope that you will give us voice.

Your obedient servant,

JOHN COLLINS, M.D., OF PODUNK.

REPORTED MORTALITY FOR THE WEEK ENDING SEPTEMBER 4, 1886.

Deaths reported 1,279: under five years of age 616: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 382, consumption 141, lung diseases 60, diarrhœal diseases 240, diphtheria and croup 55, typhoid fever 29, whooping-cough 21, malarial fever 16, measles seven, scarlet fever seven, cerebro-spinal meningitis three, puerperal fever three, erysipelas one. From whooping-cough, Brooklyn 11, Pittsburgh three, Baltimore two, District of Columbia, Nashville, Charleston, Lowell, and Newton one each. From malarial fevers, Baltimore seven, Charleston four, Brooklyn three, District of Columbia two. From measles, Brooklyn three, Baltimore, Pittsburgh, Cambridge and Chelsea one each. From cerebro-spinal meningitis, District of Columbia two, Lowell one. From scarlet fever, Pittsburgh four, Cincinnati two, Lowell one. From puerperal fever, Brooklyn, Cincinnati and Nashville, one each. From erysipelas, District of Columbia one.

In the 22 cities and greater towns of Massachusetts, with a population of 1,037,445 (population of the State 1,941,465), the total death-rate for the week was 20.51 against 22.88 and 24.21 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending August 21th the death-rate was 19.5. Deaths reported 3,400: infants under one year of age 1.264; acute diseases of the respiratory organs (London) 151, diarrhœa 606, whooping-cough 52, measles 49, fever 40, scarlet fever 32, diphtheria 26.

The death-rates ranged from 11.9 in Derby to 36.8 in Norwich; Birkenhead 27.9; Birmingham 18.9; Hull 16.3; Leeds 18.6; Leicester 24.3; Liverpool 28.9; London 17.9; Manchester 20.2; Nottingham 16.8; Sheffield 20.3; Sunderland 23.7.

In Edinburgh 15.6; Glasgow 20.6; Dublin 21.9.

For the week ending August 21th, in the Swiss towns, there were 20 deaths from consumption, diarrhœal diseases 14, lung diseases eight, whooping-cough six, puerperal fever three, scarlet fever and erysipelas each two.

The death-rates were: at Zurich 3.8; Geneva 15.1; Basle 15.5; Berne 18.2.

The meteorological record for week ending September 4, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING SEPTEMBER 11, 1886.

DICKSON, S. H., passed assistant surgeon. Detached from the Naval Academy, October 1, 1886, and ordered to Navy Yard, Washington.

LIPPINCOTT, J. G., passed assistant surgeon. Ordered to Naval Academy, October 1st.

SHIPPEN, E., medical director. Detached from Naval Hospital, Philadelphia, and ordered to attend officers of the Navy and Marine Corps at Philadelphia, not otherwise provided with medical aid.

HORD, WM. T., medical director. Detached from Examining and Retiring Boards, at Washington, October 5th, and ordered to Naval Hospital, Philadelphia, Pa.

DEAN, R. C., medical director. Ordered to duty as member of Examining and Retiring Boards at Washington, October 5, 1886.

BRANSFORD, J. F., surgeon. Detached from United States Steamship "Iroquois," and ordered to Naval Hospital, New York.

HALL, C. H. H., passed assistant surgeon. Detached from Naval Hospital, New York, and ordered to Naval Hospital, Yokohama, per steamer of 21st inst.

WOODRUFF, C. E., assistant surgeon. Ordered to Receiving Ship "Vermont," October 4, 1886.

ATLEE, L. W., assistant surgeon. Detached from the "Vermont," and ordered to the "Quinnebaug," per steamer of 25th inst.

BOGERT, E. S., medical inspector. Detached from the "Trenton," and placed on waiting orders.

FEREBEE, N. McP., surgeon. Detached from the "Trenton," and placed on waiting orders.

BIDDLE, C., passed assistant surgeon. Detached from the "Trenton," and placed on waiting orders.

SCOTT, H. B., assistant surgeon. Detached from the "Trenton," and placed on waiting orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE HOSPITAL SERVICE FOR THE THREE WEEKS ENDING SEPTEMBER 4, 1886.

BAILHACHE, P. H., surgeon. To proceed to Cape Charles Quarantine as inspector, August 27, 1886.

FESSENDEN, C. S. D., surgeon Granted leave of absence for thirty days, August 30, 1886.

GODFREY, JOHN, surgeon. To proceed to Biloxi, Miss., and investigate alleged yellow-fever cases, September 1, 1886.

IRWIN, FAIRFAX, passed assistant surgeon. Granted leave of absence for thirty days, September 2, 1886.

DEATH.

Died, at Bar Harbor, Me., September 2, 1886, Charles Dudley Homans, M.D., M.M.S.S., of Boston, aged sixty years.

OBITUARY.—DR. CHARLES D. HOMANS.

Dr. Charles Dudley Homans of Boston died at Mt Desert on Thursday, September 2d. He was born in Brookfield in 1826, and was a son of Dr. John Homans. He was graduated from the Boston Latin School, and subsequently from Harvard College, in the class of 1846, a class which included among its members Calvin Ellis, George Frisbie Hoar, and Charles Eliot Norton. After his graduation from the Harvard Medical School in 1849, he studied in Paris and on his return commenced to practise his profession in Boston, and has continued in active practice up to the present time. He was one of the original appointments to the surgical staff of the City Hospital, and at the time of his death was the senior surgeon of that institution. He was president of the Massachusetts Medical Society in 1884 and 1885, an office which his father had previously held. He was, at the time of his death, president of the Massachusetts Humane Society, and was by direct descent a member of the Society of the Cincinnati, his grandfather having been a surgeon at the battle of Bunker Hill and throughout the Revolutionary war. He was also President of the Massachusetts Charitable Eye and Ear Infirmary, a Trustee of the Massachusetts School for the Feeble Minded, and held many other positions of trust. During the war he was one of the Massachusetts surgeons who went to the assistance of their overworked brethren at the front during the peninsular campaign. Dr. Homans leaves a wife (a daughter of the late Rev. Dr. Samuel K. Lothrop) and two children, a daughter and a son, Dr. John Homans, 2d, who is already established as a physician in Boston. The health of Dr. Homans has been gradually undermined during the past few years by a series of accidents,—a broken leg, an assault by an unknown assailant in the street, and a scratch received during a surgical operation at the hospital followed by unpleasant and serious symptoms, and which had rendered his friends anxious, but which he had apparently surmounted. His death was finally due to an occlusion of the gall duct and consequent jaundice. Dr. Homans was possessed of a high sense of honor and of an exalted idea of the dignity of his profession. He had a straightforward way of looking at matters which often easily solved apparent difficulties, and gave to his conversation a directness and a force which was characteristic. Though he played an important part in affairs connected with his profession and the public, his life was singularly quiet and uneventful. He was greatly attached to his work at the hospital and faithfully and punctiliously performed the duties of his position. The younger members of the surgical staff of the hospital are particularly indebted to him for a courteous support which was unwearied, and of late years for an example of the cheerful performance of duty under difficulties, which they will be slow to forget.

RESOLUTIONS IN MEMORY OF CHARLES D. HOMANS, M.D.

The Committee of the staff of the Boston City Hospital, appointed September 4th, report the following resolution:

The surgeons and physicians of the Boston City Hospital, sensible of the great loss which they have sustained in the death of their late colleague, Dr. Charles D. Homans, desire to place on record their appreciation of his distinguished services and his character.

Connected as he was with the hospital from its foundation, his fidelity to its interests and his conscientious attention to its laborious duties, even after his health had become impaired by surgical exposure in its wards, deserve our deepest admiration and respect.

A clear common-sense, which by a single sentence could settle differences of opinion in cases of doubt, and which was characteristic of him — a wide experience — a high sense of professional honor and a constant courtesy to all, combined to render his loss one of no common magnitude, not only to the hospital service and to the sufferers in its wards but no less to its professional staff.

DAVID W. CHEEVER,
GEO. H. LYMAN,
GEO. W. GAY,
Committee.

CLINICAL NOTES ON SCABIES.[1]

BY F. B. GREENOUGH, M.D.

UNITED STATES ARMY

At the present time, scabies is, or certainly ought to be, one of the most thoroughly understood of cutaneous diseases, as to its cause, symptoms, course, treatment, etc., and it is with no hope of giving any new information on the subject that I have compiled the following brief clinical notes. Having had, however, the chance during the past few years of seeing a large, and recently a steadily-increasing number of cases, I have been much interested in the subject, and have thought it might perhaps not be entirely useless to record some of the facts to which my attention has been especially called. I wish to premise, however, that I have no intention of attempting to give a full account of a disease which is so well known to the profession as scabies, but shall simply refer to those points which have especially struck me, as being interesting in the quite large number of cases seen.

That scabies is much more prevalent at present than formerly in Boston and its vicinity, is shown not only by my individual experience, but by that of my colleagues who have charge of hospital dermatological services, as well as by the testimony of general practitioners. The probable reason for this very decided increase is to me one of the most interesting points of the subject. Scabies being contagious, its propagation to persons thrown into intimate relations with the individual who suffers from it is to be expected, but why, after being for some years comparatively rarely seen, it should all at once take a start, and increase in frequency very rapidly, is not so easily explained.

During and immediately after the war, as would be naturally expected, it was quite prevalent, and undoubtedly the large number of medical men who were connected with our army and navy service learned to recognize and treat it, and carried their knowledge of the disease with them into the practice which they settled into after the war was over. It certainly is a fact that for some years after the war, the disease became more rare, and it seems fair to assume that it was more rarely seen, because when seen it was generally recognized and properly treated. The new generation of medical men that heard little, and saw less of it, would naturally not always recognize it, and of course, every case that was not recognized became a focus of contagion. Whatever the cause may be, there can be no question but what scabies has increased in prevalency most decidedly, at least in Boston and its neighborhood. That such is the case the following figures will show. The special service for skin diseases at the Boston Dispensary was started July 1, 1873, and I had the honor of being put in charge of it. I saw, during the

1st year,	up to July 1,	1874,	. .	14	cases of	scabies.

				540		

[1] Read at the meeting of the American Dermatological Association, August 25, 1886.

The proportion which these cases of scabies bear to the number of cases of skin disease seen is as follows. I did not at first tabulate my whole number of cases yearly, but waited until I had 5,000 cases before doing so. These 5,000 cases covered, in time, from July 1, 1873, to November 25, 1876, and of these 5,000 cases 55 were of scabies, making a percentage of 1.1 per cent. From November 26, 1876, to June 30, 1878, I saw 2,494 cases of skin disease, of which eight were scabies, making 13 + per cent. After that date I recorded the cases yearly, the result being as follows:

From July 1,	1878,	to June 30,	1879,	total	872,	scabies	3 = .3+ %
"	1879,	"	1880,	"	804,	"	10 = 1.2+ %
"	1880,	"	1881,	"	1,023,	"	8 = .8— %
"	1881,	"	1882,	"	1,088,	"	21 = 2.0+ %
"	1882,	"	1883,	"	881,	"	39 = 4.0+ %
"	1883,	"	1884,	"	1,063,	"	85 = 8.0— %
"	1884,	"	1885,	"	1,299,	"	176 = 12.0+ %
"	1885,	"	1886,	"	1,220,	"	160 = 13.0+ %

From these figures it will be seen that while from November 26, 1876, to June 30, 1878, the percentage of scabies to other cases of skin disease seen was a little over three-tenths per cent., during the last dermatological year it rose to over thirteen per cent. During the past year I have asked the patients with regard to the number of similar cases in the same family or household which I had not seen, and, as a result, have 110 cases recorded as existing in addition to the 160 seen. These make, with six that I have seen in my private practice, 276 cases of scabies that have come under my cognizance in the past year. Up to three years ago, I had never seen a case of scabies in private practice. Those that I have seen since belonged to a class in which one would not expect to find this disease. From one of them I learned that in a neighboring small city the disease had become quite prevalent in an upper and decidedly exclusive social circle, affecting ladies, as well as men, and it seemed pretty evident that a very popular young gentleman had been the innocent source of the epidemic, he having brought the disease home with him from a yachting trip.

Considering the contagiousness of this disease, the fact that it is by no means self-limited, and the free circulation which exists between our cities and the county districts, the existence of such a number of foci of contagion might prove a source of serious trouble, especially if they were scattered over farms, in lumber camps or factories, where they would be brought in close contact with others, and where the disease would not be apt to be recognized. Since the end of our dermatological year, I have seen, in private practice, three more cases, two of them young gentlemen who had just finished their college course, and have incidentally heard of several others.

Scabies is, of course, not a disease that endangers the health of the community, nevertheless it is one that, if once well started, might be a source of infinite trouble and annoyance. If it should continue to increase, it seems to me that it would be well worth the while of our Boards of Health to take what steps they could towards controlling it. At least, some intelligent supervision of the children in our public schools might be attempted, and one of the most fertile sources of infection controlled. It would seem, however, that the increase of the disease has about reached its climax, as after an annual augmentation since 1881 yearly, from 0.8, 2 +, 4 +, 8, 12 +, last year it was 13 + per cent. Of the 549 cases seen, 339 were males,

and 210 females, respectively, about 60 and 40 per cent. The ages of the cases seen were as follows:

Under 1 year old, (1 each of 4, 5 and 6 mos., and 2 of 9 mos.)				5
Between	1 and	5	years,	26
"	5 "	10	"	65
"	10 "	15	"	75
"	15 "	20	"	85
"	20 "	30	"	182
"	30 "	40	"	62
"	40 "	50	"	23
"	50 "	60	"	12
"	60 "	70	"	5
70		80	"	1
				549

From this table it would appear that the disease is essentially one of childhood and early adult age, very nearly four-fifths of the cases, that is, 417 out of 549, occurring in patients between the ages of 5 and 30, and that after 50 it is comparatively rare, as only 16 cases were seen who were over 50 years old. This seems to be rationally explained by the fact of the epidermis in advanced life becoming harder and dryer, and consequently not being so well suited for the nourishment and propagation of the acarus.

The class of the community from which the bulk of these patients have been drawn, has been a matter of interest and surprise to me, it not having been that which one would expect. The children, as a rule, have been scholars in the public schools, and that is natural enough, but they have, with few exceptions, belonged to rather the better class of public school pupils, that is to say, they have been nicely, or at least cleanly dressed. The adult females, with the exception of some girls who worked in rooms where several of them were brought in contact with each other, were mothers of families, who had probably been infected by their children or husbands. The adult males have been, almost without exception, artizans or mechanics of the better class. Certainly the classes of tramps, beggars and low prostitutes have been conspicuous by their absence from the list of those seeking treatment for this disease. In most of the cases that were not married, both male and female, there was generally the history of a room mate, if not a bed-fellow, and I have no doubt but what the spread of the disease is in a measure due to the custom which young people, who are working for a living, have, of diminishing their expenses by sharing a room in common. One of the points that has struck me as most marked in the cases I have seen, is the comparative rarity of typical burrows. When I say comparative, I mean as compared with the cases I have seen in Vienna, Paris and London. I do not think I am at all overstating it when I say that even in well-developed cases of scabies, it has been decidedly the exception when I have been able to find a good specimen of a burrow. Whether this shows that our patients wash their hands more frequently and more thoroughly than those abroad, I am not prepared to say, but of the fact I have no question. The wrist, on its flexor side, in the fold of the skin made at the ulnar-carpal articulation in the vicinity of the styloid process, has seemed to me to be a more constant territory on which to find, if not burrows, at least the characteristic vesicles than even the classic region between the fingers. In the male subject the penis furnishes a most important field for examination. In a case that seemed to be at all fully developed I should consider the presence or absence of efflorescences on this organ as a most important diagnostic sign. The lesions found there are also very characteristic. On the shaft, or anywhere on the prepuce, I have seen perfect burrows oftener than any where else. As a rule, the lesions are papules, which may have a burrow on them, or may have become pustular or may be simply red papules, with a perfectly smooth and unbroken surface. I have, on the other hand, seen in this situation serpentine burrows without any signs of congestion, or exudation. In subjects where the glans is uncovered, papules may be found on it, which sometimes are pustular, but I have never seen a burrow on the glans, nor have I ever seen any efflorescence due to scabies, on a glans which was habitually covered by a long prepuce, that is, where the integument of the glans was a true mucous membrane. It was owing to the existence of these lesions on the penis that several patients came for medical advice, thinking that they had some venereal trouble, some of whom had already been put on constitutional treatment for syphilis. In spite of the most careful searching, I have never been able to find anything resembling a burrow outside of the region of hands, wrists and penis, except in cases of infants, on whose feet, especially in the vicinity of the ankles, I have seen very typical ones.

The secondary, if I may use the term, or artificial, lesions in scabies, that is those that are caused by scratching and rubbing, vary in the different regions of the cutis on which they are developed. This difference, although perhaps only one of degree, is pretty constantly seen in most cases. The regions most likely to show these lesions, are, the forearms, especially about the elbow, over the supinator muscles, the gluteal region, the abdominal walls, the anterior aspect of the thighs, and the lower leg. Given a general irritation of the skin, these regions, in the order named, are certainly the easiest to scratch. This is especially true with regard to the elbow, and in point of fact, it is in this locality that the result of irritation is most manifest. In this situation we frequently see a patch of crusty eczema, exactly like that observed on the cheeks or forehead of infants. In the gluteal region the scratching is more likely to cause single lesions, more like impetigo, even approaching a furuncular character, while on the anterior aspect of the thighs and lower legs, as is also the case on the abdominal walls, the lesions consist of small papules the apex of which has generally been scratched off.

I take it that the reason of constantly finding an eruption of an eczematous character about the elbows, is that from its situation it can be scratched or rubbed by day as well as night, but that the scratching is generally done outside of the sleeve, whereas in the other regions mentioned, at least during the night, the finger-nails get at the bare skin, and excoriate the raised papules. The aggravation of the itching after going to bed is one of the most constant symptoms complained of. It is generally ascribed to the heat of the bed-clothes, but I think that is not the only factor. Patients will state that any violent exercise, or getting heated in any way, will increase the pruritus, but not to the extent to which it is aggravated nightly on their retiring. It seems to me perfectly plausible to assume that during the night when the patient is quiet and seeking sleep, would be the time when the acari would be most active in getting their nourishment and moving about. Perhaps, also, the ease with which the itching regions can be scratched at this time, should be taken into consideration.

Be this as it may, the fact of the cutaneous irritation being decidedly increased after going to bed, is a very constant and important diagnostic sign. Any practitioner of medicine who has seen many cases of scabies, will in the great majority of those that are brought under his observation make his diagnosis from the general appearance of the case, that is to say, he will say to himself, this is a case of scabies, because it is, exactly as when we see a horse, we know it is a horse, and do not go through the process of deciding that it cannot be a cow because it has no horns, or a pig, because its hoofs are not split, etc.

Cases do occur, however, where the diagnosis is not so easy, and the ability to differentiate it is important. During the past two years I have seen several cases which I have diagnosticated, treated and cured as scabies, which if I had seen ten years ago when the disease was comparatively rare, I should not have recognized. As the disease is by no means a self-limited one, and each case is a possible or even a probable source of contagion to those who are brought in contact with it in early life, it certainly is a matter of considerable public importance that it should be diagnosticated and cured, and luckily it is one of the unfortunately few diseases that we can pretty confidently claim to be able to cure. That personal cleanliness, bathing, change of linen, etc., act as prophylactics, I suppose we must admit. I have no question but what I myself had a slight attack of scabies during the past winter. I had seen and handled many cases, and had handled them pretty thoroughly, as I was anxious to see if I could find any burrows in the general integument. I certainly had a great deal of itching between the fingers and about the wrists, and at night I scratched myself so as to make decided lesions on my forearms and shins. I never could find any characteristic appearances and just as I had made up my mind to treat myself, the symptoms gradually disappeared, as I believe, simply from the use of soap and water, in my daily bath. On the other hand, I had quite recently seen a young Harvard graduate, decidedly a swell, who tubbed it as much as any anglo-maniac and probably changed his linen daily, who was suffering with a very generally-developed case of itch.

In a few instances I have seen what would lead one to suppose that a personal susceptibility might have some influence. That is to say, I have seen two mothers of families of several children, all of whom had the disease, and yet the mothers escaped. I also have seen a child out of a large family affected, free from the disease although it was thrown in with the others, and in one instance, slept with an infected member of the family.

The finding a burrow in any suspected case, of course settles the diagnosis, but in my experience the cases in which this can be seen are not common. The distribution of the manifestations of the disease is what *we* have to fall back upon, and this is usually quite characteristic. If burrows are not to be seen, small vesicles, which are almost as characteristic, will be seen between the fingers on the ball of the hand, and at the wrist, with more or less lesions on the forearms, abdomen, gluteal regions and legs, according to the duration or severity of the attack. The condition of other members of the family is important, and the nocturnal aggravation of the itching should be taken into account. With regard to differential diagnosis, scabies might be, and without doubt, often is, confounded with any of the cutaneous diseases which have pruritus as a prominent symptom, and strange to say, its manifestations on the cutis, have in several cases which have come under my observation, been taken for those of syphilis, in which the absence of itching is universally noted. This mistake has been made not only by the patients, but by physicians, whom they had consulted. One would suppose that the irritation of the skin produced by the presence of vermin, that is, pediculi vestimentorum, would be very much of the same kind as that due to the presence of the acarus. The manifestations, however, of these two parasites are quite distinct, and can be easily recognized. The chief difference is to be found in the locality where the results of the irritation are seen. The body-louse, having its habitat on the clothing, irritates that part of the skin with which the clothes are most constantly in contact, that is to say, the shoulders, breast and waist — the uncovered hands not being affected at all. I should say also that the lesions, produced by scratching in cases of pediculosis, have decidedly a greater tendency towards a furuncular inflammation, and the pigmentation of the regions affected is much more marked. It is difficult to form an idea as to the comparative degree of itching from the account given by the patients, but I certainly have never seen the deep excoriations made by the finger-nails in cases of scabies that I have in patients infested with body-lice. As my figures have shown, the aged are comparatively exempt from scabies, whereas the victims of pediculi vestimentation are, as a rule, well along in life. I have been very much astonished by the fact that I have never seen a patient who was afflicted by the itch and body-lice, simultaneously, as one would suppose that the same influences that would expose them to the contagion of the one, would also to that of the other, that is to say, lack of cleanliness, and being thrown in contact with people of similar habits.

It is not easy to determine sometimes whether we have a case of commencing scabies, or one of hyperæsthesia or pruritus. As in cases of general pruritus the regions most easily scratched show most the results of scratching, we find in them the forearms, abdomen, gluteal regions and legs excoriated, very much in the same way as we do in cases of scabies. These cases however, are usually found in old people (pruritus senilis), where the age would be against scabies, or are due to a retention of the biliary secretion, in which case we should have the icterus to guide us.

I will not take time to refer to the differential diagnosis between scabies and urticaria, acute papular eczema, prickly heat, etc., but will merely say that scabies ought to be recognized (although my experience would show that it by no means always is) by the fact of lesions being found between the fingers, on the ball of the hand, and wrists, if not characteristic burrows, at least small vesicles; by the presence of characteristic lesions on the penis in the male subject; by the existence of secondary manifestations on the forearms, buttocks, abdomen, thighs and legs, more or less developed, as the case is of longer or shorter standing; by a decided increase of discomfort in the way of itching during the night, and by the fact that others who are thrown into intimate relations with the patient, are similarly affected. That it is important that it should be recognized and treated, I do not think that there can be any question of. I have been very much surprised by the success of

treatment in these cases. It has been so successful in my dispensary work that I have, as a rule, used the same method in private practice. The formula that I have used is the old sulphur ointment that Hardy introduced years ago at the St. Louis, one part of carbonate of potash, two of sulphur, and three of vehicle, for which I have taken petroleum ointment instead of lard, and I can not help thinking that its efficacy has been increased by the change. The objection to the use of sulphur is, of course, its irritating action on the eczematous and pustular secondary eruptions. I have, however, used it in the great majority of the five hundred and forty-nine cases I have seen, and with very good results. We were, until a couple of years ago, only allowed at the dispensary to order a half ounce of ointment, but now we can dispense two ounces. When one thinks of what two ounces will do in the way of treatment for a patient who is pretty well covered with the eruption, it certainly seems extraordinary that very few cases prove obstinate, as has been the fact. My instructions are to grease the hands thoroughly and a hand's breadth above the wrists nightly, and to apply it on the lesions on the trunk and limbs here and there, avoiding however any pustular or excoriative regions. In private practice I have ordered oxide of zinc ointment to be applied to the eczematous patches, and, even without any treatment, as a rule, these heal rapidly when the sulphur ointment has been used elsewhere for a few nights; I also, of course, giving directions as to baths, use of soaps, etc. There are, of course, more elegant preparations, but this does not stain clothing, and does its work; in fact, one of the most interesting results of my observations of these cases of scabies has been the decided success of treatment. In speaking so decidedly as to the usual success of treatment, I do not wish to be understood, as regarding the disease a simple one to treat; on the contrary, I have been very much surprised at this success especially in a class of patients that are not of the most cleanly, and without doubt, many cases have relapsed, or perhaps not even improved much, which I never have seen again. I think that one of the most important lessons to be got from a study of scabies, is the great advantage that would be gained to the community if such patients could be thoroughly treated by skilled employees of the hospitals and dispensaries, to apply the topical treatment properly, and if baths could be furnished for them. These, and a skilled supervision of schools, factories, workshops, jails and even general hospitals, would certainly furnish a great help in controlling if not stamping out the disease. The other points of interest to me, to which I have attempted to call attention, are, the fact of the increasing prevalence of a disease that ought to be, as a rule, so easily recognized; the rarity of typical burrows; the constancy of characteristic lesions on the penis in male subjects, and the difference of the secondary manifestations, according to the region of the cutis, they are developed upon.

— A lady who lost $60,000 at Monte Carlo recently, committed suicide. This is said to make the seventy-sixth case of suicide, owing to losses at gambling, from the beginning of the present season up to about the middle of August. In the last eight years there have been 1,820 suicides at that place.

THE DUNBAR TRAGEDY: WAS IT A MURDER, OR WAS IT A SUICIDE?[1]

BY D. B. N. FISH, M.D., OF AMHERST, MASS.

THIS case came under the observation of a medical examiner in a county adjoining mine, and my interest in it arose from facts learned by me during attendance at the inquest.

If, in the view here taken of it, I differ from some of my medical brethren, it is done in no spirit of criticism, for I realize the fact that it will probably never be determined by positive evidence whether this was a suicide or a murder, and that every one who forms an opinion will do it from his estimate of the probabilities in the case.

About ten o'clock on the night of the 4th of July, when the sound of a pistol-shot would attract little attention, a man was found upon a side street of a populous town, lying on the ground; the face rested on its left side, the body on the chest and abdomen. At first it was thought he was drunk; soon it was found that he was dead. On examination, a bullet-wound, which was apparently the cause of death, was discovered in the back of his head.

At the autopsy it was demonstrated that "the bullet had entered the head just under the occipital protuberance and just to the right of the median line. The skull was splintered at the point of entrance of the ball. The bullet had passed from the point of entrance upward and forward, and slightly to the right, till it reached a point a little forward of the middle of the skull, from one inch to one inch and a half, to the right of the middle line; then it passed downward, forward, and to the left at quite a sharp angle, and was found in the brain substance over the sphenoid bone, about one and a half inches from the forehead. The skull at the point of entrance was very thick, solid and fine-grained. The left hemisphere of the brain was perfectly normal. The socket of the left eye was found to contain a large clot of blood. It was impossible that the bleeding caused by the bullet should have reached the socket of the left eye. The lids of the left eye were infiltrated with blood and the eye protruded from its socket. There was clotted blood in the left nares. There was no other marks of violence. The hair was not burned nor singed, nor were there any marks of powder on the scalp, the skin or the clothing. There was no abrasion of the skin about the eye or on the face. It was the opinion of all the physicians present at the autopsy that the injury to the eye was caused by a blow on the eye." It was thought that there was no fracture of the sphenoid, ethmoid or orbital plates. The right eye was normal.

Near the body, about three or four inches from the right hand, lay a revolver of a pattern called the "Defender," calibre-32, long; this held one metallic cartridge — a 32, short — and one empty cartridge-shell. To this revolver, by a peculiar arrangement which will be described further on, was fastened a strong hempen string, ninety feet in length. This string, or cord, passed under the right foot and was stretched out along the road for about fifty feet; it was attached to nothing but the weapon. In the left pocket of the coat were three cartridges similar to the one in the pistol. The coat and vest were buttoned. The two

[1] Read before the Massachusetts Medico-Legal Society, February 3, 1886.

pocket-books usually carried upon the person were missing.

From the stand-point of the medical examiner was this a murder or a suicide?

The entire absence of powder-marks, the location of the wound of entrance, the course of the ball through the brain, and the absence of the pocket-books would seem to point to the probability of murder, while the ninety feet of string was a mystery in any view of the case. The arrangement of this string can be reproduced in the following manner: Tie a long cord, about six inches from one end, around the handle of a pistol, just back of the hammer and trigger, with a hard knot directly underneath the pistol; bring both ends of the string up over the hammer and tie in a hard knot directly over the hammer; pull the string back till it slips off the hammer, and the string, with its loop, will be seen as it was found on the "Defender." This loop could not be passed over the trigger and used for firing.

That this pistol was fired within the ordinary suicide limit is disproved by the absence of the scorchings and brandings of the powder, unless it can be shown that some intervening substance had been used, or that it is possible to hold a pistol so closely to the head that no marks of the powder would be seen. One witness stated that a hat was found pressed well down upon the back of the head; others said the hat was on the ground near the body. This hat was missing soon after the tragedy, and was admitted to have been burned by a member of the family, but the medical examiner had assured himself that there was no bullet-hole in it, nor powder-marks on it. I do not believe it possible to fire a pistol so closely to the head that some of the gases will not escape and burn the hair, but if this were possible, some unburned powder would follow the ball into the brain. No grains of powder were found in the wound, and the conclusion is obvious that this shot was fired beyond the limit of the powder-marks. It would seem impossible that one could hold a pistol at such a distance, and fire it so as to send the ball into the back of the head with the upward and forward direction seen in this case. Professor Maschka, of Prague, is quoted, in the *Medico-Legal Journal*, September, 1885, page 228, as laying down the following rule: "Certain well-known appearances, such as burning, singeing, dark discoloration, and hardening of the parts close to the wound, *must* be present for a theory of suicide." This positive statement, taken in its full apparent meaning, would leave no ground for the further discussion of this question; but Caspar has shown that suicides sometimes arrange for shooting themselves at a distance, by means of a string attached to the trigger of a pistol, and I hope to prove that it is possible to shoot one's self with a pistol held in the hand at a distance beyond the limits of the powder-marks.

The black eye, with the extravasation of blood into the orbit, was considered the result of a blow over the eye, and, therefore, evidence of a murderous assault. The three cartridges in the pocket might have been placed there by a murderer to excite a suspicion of suicide, while the absence of the pocket-books seemed to indicate murder and robbery, rather than suicide.

What did the ninety feet of string mean? In the hands of a confederate, it might have served as a means of signalling that the way was or was not clear; or it might have been used to pull away the pistol after firing, in order that no weapon be found upon or near the murderer, should he be apprehended immediately after the shooting, or should miss his aim, or should be discovered and suspected before firing. It was not possible that the pistol had been fastened to the fence or the telegraph pole near by, and then fired by means of the cord by the man himself, for the blood from the bleeding wound of the head had not run down his body or his clothing, as it would have done had he removed any fastening of the cord or pistol after the fatal shot.

The hour and the place were each alike favorable for murder or for suicide. But if this was a murder, what was the use of the peculiar loop of the string on the pistol? By pulling back the hammer, the loop could be slipped over it and used to fire the pistol. The "Defender" has its half-cock so far back that such a loop will slip off the hammer just before it reaches the half-cock, and thus the hammer can be snapped down on the cartridge; but the force of the blow is so slight, that a cartridge can be fired only after repeated attempts. It is not credible that a murderer would use such a clumsy contrivance for firing, for the repeated snapping down of the hammer on the cartridge would be too much like sounding the burglar-alarm before attempting to break into a house.

It was suggested that the string might have been passed under the foot, and the pistol have been fired by the man himself, using the loop over the hammer. This also could be done, and the firing done with some degree of accuracy. Would any use of such a string enable one to hold and fire a pistol, with any degree of accuracy, at the back of the head, and this at such a distance that the powder-marks would not show? From former experiments of my own with revolvers similar to the one used, and from the teachings of the authorities, it seemed necessary that this pistol, with its .32-short cartridge, must be held at least twenty inches from the back of the head to be sure of escaping powder-marks upon some part of the head or neck (a conclusion which subsequent experiments with a "Defender" appear to verify); yet I was obliged to admit at the inquest that I could not then, either with or without the string, hold a pistol aimed at the back of the head at a distance greater than nine inches, and at this distance could not be sure of my aim. But later observation and experiment showed me a method of holding the muzzle of a pistol at even thirty inches from the back of the head with an almost absolute accuracy of aim. Held in such a way, the pistol could be fired by the use of the loop over the hammer, and the string under the foot without using the trigger, but this gave no advantage either in holding or firing the pistol, for it could be fired easier and more accurately by using the trigger alone. After experimenting for a week, I pulled the loop back and well down on the butt of the pistol, and used the string under the foot as a "guy-rope" to steady the weapon. The latter was cocked and held in the right hand at arm's length, with the muzzle pointed towards the head — somewhat as one holds a pen. The butt rested on the little finger, the handle was grasped firmly between the other fingers and the thumb, and the trigger pressed against the palm of the hand. Held in this way, a contraction of the hand, so slight as to be hardly noticed, would fire the pistol. This method of using the string furnished a rest for the weapon, and its great advantage was at once apparent. The aim would be made certain by aiming the revolver at the right eye, and then turn-

ing the head half-way round. The cord would keep the hand from moving.

Here, then, is a possible method of firing the pistol with great accuracy at the back of the head, from such a distance that the powder-marks would not show, and a method reasonably accounting for the use of the loop and string. All that seems necessary to establish the probability of this use of the cord is some evidence of such use. The shoes found on the body were worn, and apparently had been recently wet. On the sole of the right shoe (under the instep), and on the left side of the shoe, were creases which can be exactly imitated by steadying a pistol with a cord in the manner above described, held between the thumb and fore-finger of the left hand. There was no crease on the outer or right side of the shoe.

Perhaps it will not be out of place to say here that it was the sight of the loop on the cord and the creases on the shoe which led me to change my belief in the murder theory to the conviction that this was a suicide, although I could not then account for the absence of the powder-marks. I do not believe that these creases, so exactly like those appearing on my own shoe after using the cord in the way I have described, were accidentally caused by pulling on the string at the time of finding the body; the pistol would not furnish resistance enough to make so well defined a mark as was found on the bottom of the shoe.

Was there anything impossible or improbable in the location of the wound, or in the course taken by the ball, provided the pistol had been held and fired in the manner described? A pistol can be aimed and fired so that the ball will strike any given point in a line from the eye to the occipital protuberance. It could be so fired that, if the ball continued its direction after striking the skull, it would make a wound similar to the one found in this case, but to do this would require a position of the head and arm that would be unnatural and strained, and therefore improbable, because there could be no conceivable advantage in trying to give such a course to the bullet. The easiest and most natural method of holding a pistol, aimed at the right side of the back of the head, would send a ball from the right to the left side of the brain provided it was not deflected from its course. A conical ball, fired within a short distance, from a first-class revolver of medium size, will, as a rule, pass into and through the brain in a direct course, but military surgeons have recorded many exceptions to this rule.

This bullet was apparently fired from a very inferior weapon, the "Defender," which, like many of its class, will often, I may say generally, throw a ball so that it will strike wholly or partly on its side rather than on its end, and thus may make a large wound of entrance although fired within a few inches of the head. When such a bullet strikes a rounded and unequally resisting surface, like the region of the occiput, it will be very easily deflected. Considering these facts, it seems very probable that the weapon was held in the more natural position, while the ball, deflected from its original aim, took the course described. At any rate, the location of the wound and course of the bullet do not need a theory of murder to account for them.

I do not believe the condition of the left eye was necessarily the result of any murderous assault. Black eyes, as the result of accident, are so common, and the possibilities of accident in this case so great, that I believe the condition of the left eye might be safely ignored. It was thought by some, as I have said, to have been caused by a blow over the eye, inflicted by the murderer before the shooting, and was held to be one of the stronger evidences of murder; but this seemed to me improbable even when I believed in the murder theory. If it could have been caused by a murderous blow, so slight that it left no mark upon the face, it might equally well have been accidentally self-inflicted; or might have been caused by striking a stone or lump of earth on falling after the shot; or the men who first discovered the body and thought it that of a drunken man may have accidentally struck the toe of a boot against the eye before life was fairly extinct. Any of these things were possible, and, in my opinion, far more probable than the theory that it was a second wound inflicted by a murderer. To adopt the latter theory would be doing great injustice to a very skilful piece of work. If this was a murder it was done in accordance with a preconceived plan to make it appear a suicide, as shown by the use of the pistol of the victim (or at least one like it), by the string and its mark on the shoe, and by the cartridges in the pocket. A man capable of planning and executing such a master-piece would be very careful not to furnish gratuitous evidence of murder by inflicting an unnecessary wound of the eye, either before or after the shooting.

But there is another possible explanation of the condition of the eye which seems to me the most reasonable one, and this is that the extravasation of blood about the left eye was a part of the injury caused by the bullet. Ecchymosis of the lids with extravasation into the orbit of one or both eyes often occurs during whooping-cough, and has been seen after excessive vomiting. It is not infrequent after gun-shot wounds of the head, and has even been observed after a fall upon a carpeted floor. I have found but little written on the subject of "black eyes" from gun-shot wounds, and must confess that I find no record of a case exactly parallel to this in which the effusion of blood appeared upon that side alone which was apparently uninjured. In the "Medical and Surgical History of the War,"[2] are recorded several cases in which ecchymosis of the lids was noted. Among these is the case of an unknown soldier (page 204), who was found "with a penetrating fracture of both tables of the left parietal bone at the anterior superior angle . . . the right eyelid (was) ecchymosed. A puffy swelling existed in the right temporal region . . . death ensued the same evening." In the absence of any record of autopsy it cannot be known what, if any, injury was done to the right side of the head by the ball, but the case is of interest as showing the absence of ecchymosis of the eyelids on the side known to have been injured, and its presence on the other or right side.

Lieut. Lilycrantz (page 193) "was wounded by the discharge of a pistol at a distance of about four feet from his head. The ball perforated the os frontis over the right supercilliary ridge. . . . A probe, five inches long, glided easily, by its own weight, its full length directly backward through the wound without coming in contact with the ball. . . . There was considerable extravasation in the cellular tissue of the eyelids and the pupils were dilated." In this case the

[2] Part I. Surgical Volume.

ball penetrated the *right* side of the brain while the lids of both eyes were ecchymosed.

The case more nearly parallel to the one under consideration is that of President Lincoln (pp. 305, 306). The ball entered the head "about one inch below the superior curved line of the occipital bone and an inch and a half to the left of the median line of the same bone. . . . Over the left eyelid there was slight ecchymosis." This was followed by "excessive extravasation into the orbits, accompanied by great ecchymosis of the eyelids." At the autopsy it was found that "the ball entered through the occipital bone about one inch to the left of the median line and just above the left lateral sinus which it opened. . . . It then penetrated the dura mater, passed through the left posterior lobe of the cerebrum, entered the left lateral ventricle, and lodged in the white matter of the cerebrum just above the anterior portion of the left *corpus striatum*, where it was found." This was about six inches from the entrance wound. "The ventricles of the brain were full of clotted blood. A thick clot beneath the dura mater coated the right cerebral lobe. There was a smaller clot under the dura mater of the left side. . . . Both the orbital plates of the frontal bone were fractured, and the fragments pushed up toward the brain. The dura mater over these fractures was uninjured. The orbits (were) gorged with blood." In regard to this fracture of the orbital plates, Dr. Otis quotes, with approval, the opinion of Prof. T. Longmore, of Netley, from which I make the following extracts: "The ball did not strike the anterior part of the cranium yet the orbital plates of both orbits were found to be the seats of comminuted fracture. . . . This double fracture was decided to have been caused by coutre-coup. If the term coutre-coup be limited to its precise signification of counter-stroke, that is, the impression made by the stroke on the part of the cranium opposite to that directly struck by the ball, will the force of coutre-coup explain the fractures in this instance? . . . I am inclined rather to attribute the lesions mentioned to a transmitted undulatory stroke or sudden impulse of the brain-substance itself, against the thin bony layers constituting the orbitar plates." "The unusually thin orbital plates on either side," says Dr. Otis, "were exposed to the impulse of the cerebral pulp. Even if they were not fully protected by the dense supra-orbital ridges, it might be inferred that the force would be transmitted mainly to the right orbital region, or that opposite the entrance perforation. Whereas *both* orbital plates were fractured. That the fragments inclined upward toward the brain rather than downward and forward, was probably due to the pressure of the blood extravasated within the orbits."

It will be remembered that in the case which forms the subject of this paper, the ball struck against the right side of the vault of the cranium and was deflected sharply towards the left hemisphere of the brain. If the medical examiner had not assured himself that there was no fracture of bone at any point other than that of entrance, the condition of the left eye might have been easily accounted for on the theory that the force of counter-stroke, or if, with Dr. Otis and Professor Longmore, we reject this, the impulse given by the ball to the cerebral pulp had fractured the sphenoid, or the orbital plate of the left, if not of both orbits. It is possible that the effusion of blood appeared first in the left eye because of the position of the body, and that it might have appeared later on in the other had it not been checked by the advent of death. It will be remembered that in the case of President Lincoln, who lived nearly nine hours after the receipt of his injury, the ecchymosis appeared first over one eye, while *both* orbital plates were broken. If, in the case under consideration, we must exclude any fracture of bone, can we not safely admit the possibility that the impulse of the bullet upon the brain-substance may have ruptured some minute branch of the ophthalmic artery and thus caused the hæmorrhage?

Having shown, as I think, that every feature of the injury to the head could be produced by a suicidal shot, it is time for an estimate of the probabilities of the case. I can not see an objection to the suicide theory that does not bear with equal weight against the theory of murder. The former seems consistent in all its parts, while the latter seems inconsistent and in some of its requirements apparently impossible.

On the theory of suicide this man, who was known to be possessed of remarkable ingenuity, who had a few months before purchased a pistol and cartridges similar to those found on the body, who is reported to have asked when buying the pistol: "where can a man shoot himself to cause instant death?" and to have been told "in the back of the head;" — this man determines to commit suicide, and to do it in such a way as to make it appear a murder. He arranges the string on the revolver in such a way that he can shoot himself from a distance that will excite a suspicion of murder, not necessarily knowing that he could fire it beyond the limits of the powder marks. He loads his pistol with two cartridges and puts three in his pocket. He starts out and is seen on the street, but suddenly disappears from the road, or, rather, is not seen to pass a house a little further along his route; he has turned off the road to leave his empty pocket-books, folded and clasped, in plain view in the rear of a building. Perhaps he here receives an accidental injury to the eye. He then goes down to a less frequented street, drops the loose end of the string and unwinds it as he goes. Now he cocks the revolver, holds it directly out from the shoulder at arms' length, adjusts the cord and makes it taut by an almost involuntary up-and-down movement of the hands which causes the cord to crease his shoe, takes his aim by the starlight, for it was starlight, or possibly by the phosphorus from a match rubbed on the top of the barrel and sight of his pistol, turns his face over the left shoulder, presses the palm of his hand against the trigger and the deed is done.

I have been told that this scheme is too ingenious to be credible, but *somebody* thought of this method of using the string before the officers of the law came upon the scene, and if that somebody was a murderer, he had a plan which involved all this and much more. This murdered man must appear to have committed suicide, but there must be evidence on and about the body to make it appear that he had endeavored to simulate a murder. The pistol of the victim by his side, the string with its loop, the buttoned coat and vest, and the creases on his shoe (to be made after the man had fallen), will excite a suspicion of suicide, while the absence of the powder-marks will indicate that he has attempted to simulate a murder by shooting himself at a distance. How much more simple and safe to have placed the weapon to the man's head and fired. His

own pistol by his side, the three cartridges in his pocket, and the buttoned coat and vest would have pointed strongly to suicide.

I have not introduced here the supposed blow upon the eye, for I do not see where, in the theory of murder, it can come in with any degree of propriety. No man holding a loaded revolver in his hand, with the intent to shoot his victim in a comparatively public place, would first knock him down, and then stand off and shoot him from a distance. If this was a murder, the assassin, after taking incredible pains to make it appear a suicide, would never have placed the empty pocket-books where they could be easily found, and thus, by his own act, arouse a suspicion of murder.

If we adopt the theory that this was a murder, with no attempt to make it appear a suicide, we have to account for the pistol owned by the victim, for the loop on the string, for the creases on the shoe — so unlikely to have been produced by accident — for the buttoning of the coat and vest at the risk of safety, after rifling the pockets, and for the folding and clasping of one, at least, of the pocket-books after taking what little money might have been in them.

I believe that the medical examiner would have been justified in reporting this as *a case of probable suicide, but one which demanded a legal investigation.*

At the inquest it was shown that the deceased was in straitened financial circumstances, and that he had an insurance on his life of $66,000.

In his summary of this case, Judge Tucker said: "It seems clear that this death was either a murder, accompanied by an attempt to make it appear a suicide, or a suicide with an attempt to make it appear to be a murder. A careful consideration of all the facts compels me to the conclusion that Mr. Dunbar committed suicide. This theory explains all the facts but one — that exception is the injury to the left eye. The evidence leaves it doubtful whether this injury was inflicted by a blow, or was the result of the shock of the bullet-wound. If the latter theory is true, then it is not inconsistent with suicide; if the former, then suicide seems impossible."

It hardly seems probable that the judge intended to exclude the *possibility* that the injury to the left eye was caused by accident, and when he says: "If the former theory — that this injury was inflicted by a blow — is correct, then suicide seems impossible," I must suppose him to mean a blow from the hand of an assassin.

The verdict was that Mr. Dunbar "came to his death by a bullet fired from a pistol, which bullet entered the back of his head, and that said pistol was discharged by his own hand."

REPORT ON THERAPEUTICS.

BY FRANCIS H. WILLIAMS, M.D.

ERYTHROXYLON COCA AND ITS ALKALOID COCAINE.[1]

COCAINE paralyzes the sensory nerves by direct action on the terminal filaments; and later on abolishes reflex action by like effect on the posterior columns of the cord. If injected directly upon a nerve-trunk (and this is well worthy of careful notice), it paralyzes its whole distal distribution. It stimulates the respiratory centres, but death is due to asphyxia, the heart continuing to beat after breathing has ceased.

The peristaltic movements of the intestine are increased, thus acting as a mild aperient. It has no appreciable effect upon the voluntary muscle, but its action on unstriated muscular fibres is yet undetermined.

Bosworth has noticed that the drug causes very notable contraction of the nasal corpora cavernosa, "the local application over the whole membrane covering the lower and middle turbinated bones causing these sinuses to become so rigidly contracted that all the blood which they may have contained is absolutely expelled and the membrane clings closely to the bony structures, which then become visible in absolute outline."

This he has confirmed by repeated observation, and has concluded cocaine "produces rigid contraction in unstriped muscular fibres." If this is so the contraction of the capillaries, as well as the sinuses may be due to direct action on their muscular coats, a method which, if I remember right, is shared only (though with paralyzed effect) by amyl nitrite. As the erectile tissue is dominated by the sympathetic, the whole phenomena, however, are fully explained, by the established action of the drug upon that nerve.

Locally applied it has slight (if any) effect upon the skin, unless denuded of epithelium. Superficial injection causes anæsthesia of the surrounding tissue to the extent of two or three inches, but deep injections affect the skin to a much less degree. When thrown down upon a nerve-trunk, while it affects the distal distribution, the centric portion, even a short space (immediately?) above the point of puncture, is uninfluenced. Dr. Corning has found when the local circulation, in a part into which a solution of cocaine has been injected, has been arrested either by an Esmarch bandage or a tourinquet, the insensibility induced by the drug may be greatly prolonged, as thus the solution of cocaine is kept in contact with the filaments of the sensory nerves. When painted upon the mucous membranes, the tissues become paler and thinner, secretion is diminished and sensation is completely annulled, the effect being greater at the actual point of contact of the drug, and is in proportion to the strength of the solution used, and up to a certain point of the number of applications made. May this not be up to a limit of topical absorptibility (saturation)? It renders the conjunctiva and cornea completely insensible, the ischæmia of the former being well marked, whilst it passes through the latter into the anterior chamber, as fluid extracted therefrom produces similar effects upon the other eye. "In eye under cocaine intra-ocular tension is decreased, and mydriasis is increased in a bloodless eye."

It dilates the pupil by local stimulation of terminal fibres of cervical sympathetic (the mydriatic nerve), and not by paralysis of motor oculi nor of circular fibres of iris. The degree of dilation seems to vary. Knapp, of New York, reports "pupil scarcely ever become as large as with atropine."

"Accommodation is not wholly lost, the range of accommodation being shortened by recession of the near point from the eye, the far point not being appreciably influenced," its action being more upon the ciliary muscle than upon the iris (Knapp.)

As a corollary to its contraction of the capillaries, the drug may yet develop useful qualities as a hæmostatic.

[1] E. W. Holmes, M.D. Therapeutic Gazette, August 16, 1886.

The contradictory reports of the action of the remedy may be reconciled, I think, either by exceptional idiosyncrasies, or from imperfect or insufficient methods of application, or from the use of inert preparations.

It should also be remembered that cocaine, being a product of organic chemistry is liable itself to deterioration, microscopic growths nourished by the alkaloid destroying its efficacy, boric or salicylic acid being the best preventives of this change. The leaves also contain another principle, "hygrine," an active mydriatic (though cocaine seems to produce mydriasis independently of hygrine), also ecgonin, coca tannin, and coca wax, whose effects, but slightly known to us, may yet modify our conclusions. Those who are interested in chemical analysis would probably be gratified to know that the formula for cocaine is $C_{17}H_{21}NO_4$, whilst in chemical terminology cocaine is a "methylbenzomethoxyethyltetrahydropyridinecarboxylate, whilst the impurity ecgonin is merely a methoxyethyltetrahydropyridinecarboxylic acid." Mack has succeeded in transforming benzoyl ecgonin into cocaine by heating several grammes with iodide of methyl and methylic alcohol, and then evaporating. The product conforms to all tests of genuine cocaine. Some of the samples used have been found to be adulterated with eserine. The fatal dose to man has not yet been reached. Twenty grains taken with suicidal intent, produced vertigo, unsteadiness of gait, headache, nausea, vomiting, burning thirst and abdominal gripings, all of which passed off in twenty-four hours.

I have applied from f℥iv to f℥vii (gr. 15⅔) of four per cent. solution to my own buccal pharyngeal and nasal mucosa in the course of four hours, and frequently less amounts to myself and others of same strength. In the smaller amounts, say ℥ii, there is a rather pleasing sedative effect, a sensation of well-being and well-doing, of content with yourself and your surroundings, which is sufficiently marked to afford a ready inducement to further appliance. This sedation has never with me run into somnolency, though others on whom I used small amounts *seemed* to experience such result, whilst in children, relieved by cocaine from toothache or earache, sleep, I think, naturally followed the freedom from pain. In the larger amounts there is to myself a sensation of intense cerebral activity, with augmentation of thought-processes, and especially with stimulation of imaginative perceptions and fancies, and I must confess there is a certain witchery which is apt to entice one to further indulgence. Sleep is totally abolished, whilst the continued application induces the rather actual wakefulness, with further a degree of restlessness, which finally becomes almost painful.

There is also vertigo and nausea, going on to vomiting once after ℥iss, and again after ℥v had been used, and very decided tremor of the voluntary muscles interfering somewhat with the use of the pen. The skin is covered with profuse cold clammy perspiration; the pulse is bounding (120), beating full and strong; the brain is on fire, and throbs with unnatural excitement. In fact, after using the ℥vii from eight to twelve, one evening, I could only break myself from its further use by decided effort, and could not compose myself sufficiently to go to bed till about 4 A.M., where I tossed with little sleep till my usual hour of rising, and in the forenoon endured an intense prostration it has seldom been my lot to experience, which by noon compelled me to abandon my daily rounds and return home, where two or three hours' sleep restored my pristine vigor and appetite. I can appreciate now, as never before, the glamour of opium and cannabis indica and the wretchedness of after-repentance. The loss of appetite is well-marked even with smaller amounts, and this is not at all satiety; the repletion of a Thanksgiving dinner, but with slight nausea, a disgust of food, which prohibits hunger, though there is not "the hollowness" of simple abstinence from food. So far as these practical trials on myself go, I would, in view of endurance of excessive fatigue, rather depend on the latent energy of something (to me) far more substantial than cocaine. It should be remembered the above is practically overstimulation — the sudden thrust of an excess — upon an organization unused to any stupefacient, whether in the form of opium, tobacco, or alcohol; ℥i of four per cent. solution contains about gr. 2½, mxiii of four per cent. solution contains about gr. ¼, whilst a handful of leaves, say ℥i, only gives up gr. $\frac{1}{16}$ of the alkaloid. The dose by the mouth is gr. ½ to gr. ½.

The rapid sketch I have given must suffice for the most part as indication of the range of usefulness of the drug. I cannot, however, too strongly urge that the anæsthetic effects are purely local, even that upon the nerve-trunk, and the slight or negative effect upon the skin coming under this category, and that to secure the best results, sufficient care must be exercised to convey the solution to the parts indicated. It has been used successfully in operations upon the inner surface of eyelids and tear-passages, and on the eyeball in iridectomy, operations for cataract and glaucoma, and even in enucleation. As a number of failures to induce complete loss of sensibility in the last-mentioned use have been reported, allow me to add emphasis to my caution by a quotation of Turnbull's *modus operandi*:[2]

"In a case of enucleation, two drops of four per cent. solution of cocaine were instilled every three minutes until eight had been used. When Tenon's capsule was opened, one drop of the solution was allowed to flow into the cup. As each tendon was caught up in the hook, a drop fell upon it, and the successive tentomies, each being preceded by a drop, were made at deliberate intervals. The large blunt-pointed scissors, curved on the flat, were next introduced from the nasal side, and with these in position, after thorough sponging, two or three large drops were so instilled as to flow down the blades, one on each side of the optic nerve as a guide. After waiting a minute, the optic, and with it the ciliary nerves, were severed at one stroke, during which the patient remained entirely quiet. There was less than the usual bleeding, and the healing was undisturbed." (Knapp, p. 26).

Outside of ophthalmology, the field is too extended for individual mention. The journals are replete with notes of cases. Some of the less obvious may be given a passing notice. Thus it finds a favorable application in acute atitis media, in removal of small tumors from various parts of the body, and in the lancing of abscesses.

Papilloma of the larynx has been successfully removed with its aid, and operations for fistula in ano, vesico-vaginal fistulæ, and lacerated cervix and perineum have been painlessly performed. Dr. C. H. Thomas, of Philadelphia, claims for it the property of

[2] Med. and Surg. Reporter, November 9, 1884.

reducing inflammation and engorgement of the tissues in diseases of the endometrium.[3]

Circumcision has also been equally satisfactorily done. The mucous surfaces of the prepuce being first carefully cleansed, then slightly moistened, cocaine, in powder, is dusted on the surface to obviate pain from first stab of the needle, then hypodermics are given (four per cent. solution), four minims on dorsum, near frænum, and on each side (sixteen minims in all). Even a hydatid tumor of the liver has been opened and emptied under cocaine. In this case the patient was seventy-two years old, and ether was contraindicated by his general condition. Four per cent. solution was rubbed in for half an hour. Skin and subcutaneous fat passed with trivial pain. Fresh applications were necessary as muscles and peritoneum were reached. The operation lasted an hour. No shock and no peritonitis followed. Patient died on twenty-second day after operation, from inanition due to complete absence of bile from the alimentary canal. Soon after eating, the flow of bile from the sac was very great. The autopsy showed no peritonitis.

The dysphagia and violent irritative cough of laryngeal phthisis have been ameliorated, thus giving us some control not hitherto possessed over these distressing symptoms, though not the complete mastery we were led to hope for. The relief of cutting pains of first stage of labor has followed its application to tissues about the cervix, whilst its endermic use has enabled the painless passage of the head through the actium vaginæ. In senile gangrene, its application has relieved the severe pains of that dangerous disease.

In confirmation of the action upon the nerve-trunk, Dr. Nash, of New York, injected mx viii of four per cent. solution as near as possible in the infra-orbital foramen, reached through the mucous membrane of the mouth. There was complete anæsthesia of the left half of the upper lip and cheek, on both the skin and mucous surfaces; also a portion of the nose and left side of lower border of the gums, from the median line beyond the bicuspids. He inserted a gum wedge very firmly, causing no pain, and excavated and filled the tooth without giving the patient a sensation of pain, although before the injection the tooth was exquisitely sensitive. A similar result followed injection of eight minims into infra-dental nerve at point of entrance into ramus of jaw. An epithelioma has been treated by arsenical paste, the patient being readily able to endure its caustic action by reason of the remedy.

In leaving this part of my subject, I trust it has been well noted that the drug is not too rapid in its action, and that time should be given between successive applications for the preceding to take effect. Of cocaine, when taken by the stomach, I have little to say, my own experience beyond operative measures, and for irritative cough being designedly limited to its local use in hay fever, of which I have spoken elsewhere.

The fluid extract is reported to be a valuable adjunct for treatment of the morphine habit, but is not a specific. Cocaine is said to dilate the pupil contracted by morphine, and to allay the morphine hunger. In chronic alcoholism it is also serviceable, though a case reported to the Mississippi Valley Association of its treatment by gr. 1-5, hypodermically, was followed by cocaine habit, the patient using gr. x daily.

The irritation, when used hypodermically, is not greater than that from morphine, mxx to xv (four per cent. solution), usually causing no constitutional symptoms beyond vertigo, pallor, and dilatation of pupil, whilst larger ones may cause nausea and vomiting also. The effect of the drug lasts according to the strength of solution, and number and efficiency of applications. It would not be strange in a remedy of such marked peripheric force, if investigation would show a further centric impression than is at present accorded to it, but of this additional observation is necessary.

In the later journals, reports of ill effects have not failed to appear. It is said exfoliation of the corneal epithelium, vesicular keratitis, lasting several weeks, and panophthalmitis have succeeded its application. In other cases, general intoxication, nausea and vomiting, lasting an entire day, stumbling gait, syncope (cerebral anæmia?), pallor and sweating, loss of consciousness, and convulsions are said to have ensued.

In one case that came under my own notice, the use of upwards of f3i (four per cent.) applied to the nostrils was followed by a disagreeable dyspnœa (over-stimulation of respiratory centres), lasting a considerable time.

Whilst it is by no means established that all the above are surely chargeable to the drug, there is enough to make us watchful and by no means indifferent to the possible results, even though the more grave effects may be exceptional; may be from excessive quantity or from individual idiosyncrasy.

It may be worth mentioning in passing, that the case of poisoning from gr. x hypodermically,[4] resembling morphine-poisoning, is not free from suspicion, owing to the large amounts of alcoholic stimulus injected.

A number of instances of addiction to the excessive employment of the alkaloid have already been reported in our own country. Whilst we are not justified in jumping at any conclusions upon the evidence thus far presented, we are indeed urged the more to greater caution in its prescription both for others and ourselves, with added emphasis to the old adage "A man his own lawyer has a fool for a client."

Dr. Charles N. Dixon Jones, of Brooklyn, writes to the *New York Medical Record*, July 3, 1886, as follows:

"Gastric lavage is rapidly becoming our most reliable treatment in chronic dyspepsia and gastritis. In order to avoid some of the disagreeable features attending this operation, I have resorted to the following expedient: About fifteen minutes before commencing the operation the patient is allowed to hold in his mouth a piece of absorbent cotton saturated with a four per cent. solution of hydrochlorate of cocaine; in a few minutes the palate and fauces are painted with the same solution. The stomach-tube is lubricated with a mixture of olive oil, oil of wintergreen, and cocaine, after which it may be introduced and the stomach irrigated without that disagreeable vomiting of the tube and efforts at gagging which frequently attend the operation. I have adopted this method in some of the most trying and difficult cases, and always with the most happy result."

Bockharb recommends in the *Monatshefte für Praktische Dermatologie*, No. 2, 1886, cocaine as an efficient remedy for the painful tumefaction of the gums occasionally observed in the course of a mercurial treatment. A ten to twenty per cent. solution of the

[3] Am. Journ. Obstet., February, 1886.

[4] Medical Record, November, 1885.

hydrochlorate of cocaine is to be brushed over the affected part several minutes before mealtime. If the mucous membranes present (mercurial) ulcers, a five per cent. solution of cocaine suffices. The brush is to be disinfected with carbolic acid after having been used, as the solution would otherwise soon undergo decomposition through the agency of the bacteria of the mouth.

STROPHANTHIN.

Professor Fraser,[1] after a careful study of the action and uses of this substance, has published a very interesting and valuable account of his experiences as well as the excellent results of its use in a number of cases. He is of the opinion that if a substance could be obtained which exerts a more powerful action upon the heart, and at the same time produces fewer secondary actions, it is not improbable that therapeutic experience would prove it to be a valuable substitute for digitalis, and would even place it in a higher position as a remedy than that substance. This anticipation is to some extent supported by the examination of strophanthus (hispidus?) which is used in equatorial Africa as an arrow poison. The seeds are very active, and, when coarsely ground and formed into a paste, they constitute the poison with which the arrows are smeared. When examining the chemical properties of the seeds Professor Fraser easily separated a crystalline body, having a strangely bitter taste, readily soluble in water, of a feebly acid reaction. It does not contain nitrogen, and when heated with dilute sulphuric acid it yields glucose and a body insoluble in water.

The pharmacological action of strophanthus appears to be an extremely simple one, and may be described by calling it a muscle-poison. However introduced into the body, it increases the contractile power of all striped muscles and renders their contractions more complete and prolonged. As a result of the action on muscle, the heart is powerfully affected.

The changes which occur in the heart's action are the ordinary changes that have been frequently described in the case of digitalis, and they are accompanied by a rise in blood-pressure, which appears to be directly produced by them, and, in certain conditions, by an increased secretion of urine, and a reduction of temperature.

Strophanthus was administered with a view of discovering whether it would serve as a substitute for digitalis. This has been done in a large number of cases, a few of which are reported in the original paper with pulse tracings which are very flattering to this new drug.

The impression received from a number of cases suggested that strophanthus is more powerful and more rapid in its action than digitalis. As it is difficult, by chemical observation alone, to prove the existence of differences between remedies that act in a similar manner, Professor Fraser determined to ascertain if any important pharmacological differences could be discovered, and experiments were made to define the energy of this action on the part of digitalis and of strophanthus. For this purpose, the separated frog's heart was used, and it was supplied with solutions of each substance by means of Williams' apparatus. It was found that solutions of digitalis of 1 part in 100,000, 1 part in 50,000, 1 part in 10,000, 1 part in 5,000, and of 1 part in 4,000, each produced characteristic changes in the heart's action but were not strong enough to kill the heart within two hours. With strophanthin, on the other hand, a solution of 1 part in 100,000 quickly stopped the heart's action in extreme systole. solutions of 1 part in 250,000, of 1 part in 500,000, of 1 part in 1,000,000, up to 1 part in 10,000,000, were each tried, with the result that the heart was characteristically affected, and killed by each of them.

Assuming that the digitalin was a fairly representative specimen of that substance, these experiments point to a very striking difference between strophanthin and digitalin, in reference to their power of producing the changes in the heart's action, which constitute a most important feature in the therapeutic applications of the members of the digitalis group.

It seems probable that strophanthin differs also from digitalin by acting more on the heart and less on the bloodvessels than digitalis.

The experience thus far obtained shows that sickness and gastro-intestinal disturbances are not produced so frequently by strophanthus as by digitalis, nor has intolerance occurred after its uninterrupted administration for several weeks.

The original article deserves careful study from those who are interested in this subject as in it are the mature results of Professor Fraser's labors extending over a long time; the first publications by him on this subject were made in 1870.

(To be continued.)

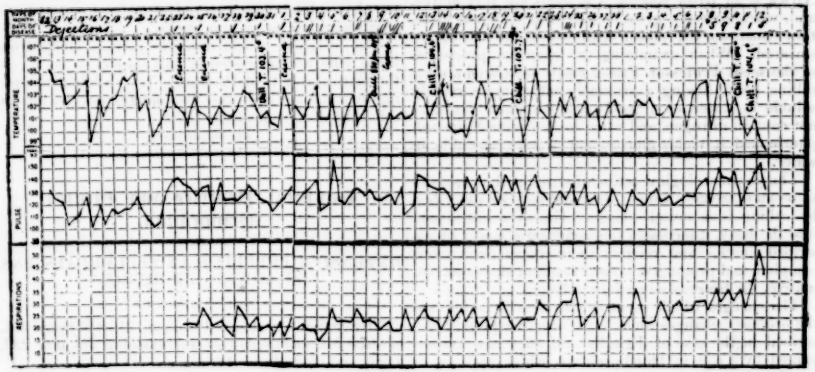
Hospital Practice and Clinical Memoranda.

EXTENSIVE PHLEBITIS AND PELVIC ABSCESS, FOLLOWING ABORTION.[1]

BY FRANCIS MINOT, M.D.

The patient, a married woman, thirty years old, entered Massachusetts General Hospital January 23d, 1886, and died March 12th.



Five weeks before entrance she aborted at the third month, without assignable cause. She stated that the entire ovum came away, but she had much flowing for several days. Two weeks after the abortion she had a chill, and another a week later, with vomiting, diarrhœa, pain in the pelvis, and painful micturition. The left lower extremity became painful, swollen and numb.

The patient was much emaciated, with a sallow complexion, and anxious expression. The pulse was small and feeble. There was no evidence of disease in the lungs or heart. The entire left lower extremity was swollen, œdematous and white. There was a small ulcer on the lower part of the calf, resulting from the application of a hot stove-cover during one of the chills. There was much tenderness, especially in the saphenous region and in the calf. No hypogastric tenderness. No vaginal discharge. After January 31st, there was a slight improvement for a few days, and then there was pain in the right calf. The slough on the left leg increased, and another formed on the heel, and the patient slowly failed in strength. Nothing abnormal was detected by digital

[1] Read before the Obstetrical Society of Boston, May 8, 1886.

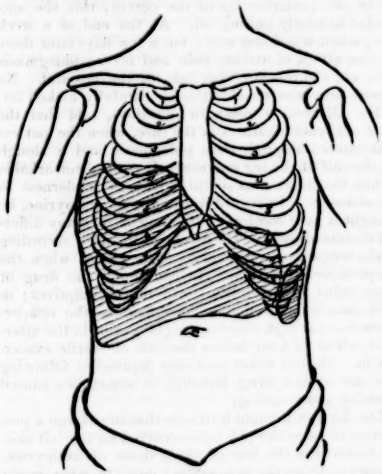
examination on February 5th. There were chills from time to time, with rapid pulse, high temperature and involuntary dejections. The œdema and the pain in the left leg began to diminish February 14th, but there was no general improvement. There was enlargement of the spleen. On March 7th she was much more comfortable than usual, but on the 8th she had several small, yellowish, and very offensive dejections, containing pus but no blood, and without pain, which continued till her death on the 12th, with symptoms and physical signs of pulmonary œdema; about seven weeks after her entrance into the hospital, and twelve weeks after the abortion.

Autopsy by Dr. Fitz. The inferior vena cava contained a completely obstructing thrombus in the lumbar region, adherent to the wall of the vessel. It was of a reddish color, and tubular, with fluid puriform contents. It extended upwards as far as the liver, as a yellowish-white, parietal thrombus; and downward into the right femoral vein as a completely obstructing thrombus, the centre being softened, like the portion higher up. The left iliac vein was completely obstructed by a pale-red, translucent fibrous plug. The walls of these veins, especially the left iliac, were intimately adherent to the surrounding parts by fibrous tissue. Both renal veins contained opaque white thrombi, not completely obstructing. The uterus and left broad ligament were intimately united to the pelvic wall and left half of the rectum. The left ureter and left third of the posterior wall of the bladder were adherent to the surface of the uterus and pelvic wall toward the base of the peritoneal cul-de-sac. In detaching the uterus from its adhesions the cavity of an abscess, with shreddy walls and offensive reddish-yellow contents, was opened. It extended from between the bladder and vagina to the left side of the pelvis, as far as the brim of the pelvis, and followed the surface of the iliac muscles. A limited purulent infiltration was found just below the bifurcation of the aorta. Near the brim of the pelvis the abscess communicated by a hole with the rectum. The uterus was slightly enlarged; its tissue presented no abnormal appearance. The Fallopian tubes were normal, except that the fimbriated extremity of the left

one was adherent to the wall of the abscess, and was covered with a patch of false membrane. The left ovary was intimately connected with the abscess-wall; it was enlarged to the size of an almond, flaccid, and its surface was wrinkled. On section it showed pus cavities and diffuse purulent infiltration. The right ovary showed nothing abnormal. The left broad ligament was almost wholly destroyed, except the portion covering the Fallopian tube, which was swollen and injected. The lungs were extensively œdematous in the lower and posterior portions. In the secondary branches of the right pulmonary artery were soft, opaque, yellow emboli, moderately adherent. Similar emboli were found in the smaller branches of the pulmonary artery in both lungs. The heart, liver and kidneys showed evidence of granular degeneration. The spleen was enlarged to three times the normal size, of a pale reddish-gray color, and soft; the follicles were enlarged and distinct.

The circumstances attending the attack of phlegmasia dolens in this case were the usual ones: debility from loss of blood and probably unfavorable hygienic conditions, a chill, and painful swelling of the left leg. There was also pain in the pelvis with dysuria, and it seems probable that the starting-point of the process was a phlebitis in the uterus or its annexes. Although the patient thought that the ovum came away entire it is quite possible that some fragments may have been left behind, giving rise, under unfavorable hygienic conditions to septicæmia which was followed by thrombosis and abscess. It is remarkable that there was no special abdominal tenderness, and that no swelling was detected by internal examination. The question of laparotomy might perhaps have been entertained had the patient come earlier under treatment; but in her exhausted condition the indications for operative treatment were not encouraging, moreover the signs of pelvic inflammation were very obscure. The great irregularity of the temperature, with occasional wide oscillations, the rapid pulse and the frequent recurrence of chills, as shown by the chart, are characteristic of septicæmia.

—The building of the Medical College of the State of South Carolina was almost ruined by the late earthquakes.



HYPERTROPHIC CIRRHOSIS OF THE LIVER.[1]

BY A. L. MASON, M.D.

CASE I. Julia Poivell, aged thirty, married, a very large, fat woman, entered the City Hospital April 11, 1883. She had had one child and three miscarriages, the last within five weeks of admission. Otherwise her health had always been excellent until within two months. She had been a free drinker of beer, but her nerves were steady, and she had not the appearance of a drunkard. There had been no headache and no hæmorrhages; no chills.

When first seen the condition was as follows: intense jaundice; constant nausea and bilious vomiting soon after eating; dizziness, flatulence, and occasional diarrhœa; pain at epigastrium; slight œdema of feet and ankles. The tongue was clean; the pulse 80, temperature 97.8° F.

The urine had a sp. gr. of 1017, a deep yellowish-red color, and contained a little albumen and much

bile pigment. Sediment normal. Dejections hard, light yellow.

Physical examination showed great enlargement of the liver and spleen, the former extending from the third intercostal space nearly to the crest of the ilium, and the spleen being readily felt below the ribs. No ascites. Examination of the blood showed the red and white corpuscles in normal proportions.

Three days after entrance the epigastric pain and the vomiting were severe, and were relieved by small doses of morphine. Under this treatment, liquid diet, and the use of an alkali, the symptoms abated, and in three weeks the patient was discharged, although the jaundice continued and the liver was no smaller. The temperature never rose above 100° F.

A diagnosis of hypertrophic cirrhosis of the liver was made, which involved an unfavorable prognosis, and the patient was told to return when she found it necessary. Three months later she came back, and was under the care of Dr. Denny. She had become very weak, and was dizzy and forgetful, hardly remembering her previous stay in the hospital. Otherwise the symptoms were much the same as before — jaundice, large liver, headache, vomiting, and epigastric pain. The feet were numb, but she walked fairly. No ascites. Urine as before. Temperature 97°, pulse 108.

After a few days the appetite failed, micturition became involuntary. She was delirious, and died August 22d, after an illness of about seven months.

The autopsy was as follows:

Autopsy. Twenty hours after death; body medium-sized; abundant adipose development; marked lividity of face and dependent portions; rigor mortis present. Calvaria heavy and very dense. Sinuses contained a small amount of coagulated blood, as did also the vessels of the pia. Brain normal. Heart not much distended with blood, mitral valve admitting the tips of three fingers, tricuspid of five. Muscular substance of heart slightly fatty. Right lung œdematous throughout; left lung slightly œdematous. Spleen normal in size.

The liver extended one and a half inches below the ribs in front, and weighed six pounds four ounces. External surface smooth, with slightly greasy feeling. On section, it was firmer than normal, of a grayish, translucent appearance. Venous portions of acini marked, rather far apart, with grayish, translucent substance between.

Kidneys of usual size; capsule readily detached; surface smooth. On section, cortical portion somewhat opaque; pyramidal portion normal. Stomach and small intestines not unusual.

Large intestines very much distended with fæces. Vessels much injected. Mesenteric glands somewhat enlarged.

Diagnosis: œdema and congestion of lungs; slight fatty degeneration of heart; hypertrophic cirrhosis of liver, with slight fatty infiltration; cloudy swelling of kidneys; enlargement of mesenteric glands.

CASE II. Jennie Brennan, aged twenty-nine, married, a well-developed woman of medium size, entered the hospital April 7, 1886, in a delirious state. She had rheumatic fever four years ago, but had otherwise been healthy, and her family stated that she had not been given to excessive drink. For the last six months, however, she had suffered from debility, absence of menses, gastric derangement, and slight swelling of feet for two weeks. She had been in bed for the last six weeks, delirious a fortnight.

At the time of entrance the symptoms were very active delirium suggestive of alcoholism; slight jaundice; moderate fever; pulse 100; respiration 24. The lungs were normal, and there was a soft murmur over the præcordia. The urine was very high colored, specific gravity 1020, and contained a trace of albumen. The abdomen was tympanitic and distended, but there was no dropsy. Enlargement of the liver was not detected. The noisy condition of the patient made thorough examination somewhat difficult.

Soon after entrance she had a severe convulsion, followed by stupor, and she bit her tongue badly.

The usual remedies failed to procure sleep, delirium was constant, the condition became typhoidal, with increasing fever, parched lips and dry, brown tongue; jaundice was noticeable, and she died one week after admission about six months after the beginning of her illness.

[1] Read before the Suffolk District Medical Society, April 24, 1886.

Autopsy by Dr. Gannett. Brain and its membranes negative. Heart of usual size, flaccid, valves negative, hyperplasia of spleen. Kidneys, slight degree of œdema. Œsophagus, stomach and intestines negative.

Liver much enlarged, weighing seven pounds nine ounces. Edges rounded, showing in general a yellowish color. On section, acini fairly distinct. Central portions for the most part pale red; in other portions of a bright yellow. Peripheral portions of a pale opaque yellow. Lobules separated from each other by gray translucent network. Bile ducts pervious. Diagnosis: chronic interstitial hepatitis, with fatty infiltration.

The symptoms and pathological conditions observed in these two cases correspond almost typically with those which, in recent years, have been classed as hypertrophic cirrhosis in distinction from the ordinary contracting disease which produces the hob-nailed liver of drunkards. While the causation may be the same, the conspicuous absence of dropsy throughout with the presence of jaundice and a greatly enlarged liver and spleen, make quite a different type of disease from that which we usually see as cirrhosis.

The post-mortem appearances as described in published reports have not always held together as they should to establish a characteristic pathology, but the discrepancies have been mainly histological, which might easily arise in examinations at different stages of the liver disease. The principal morbid change consists in a great increase of bile ducts surrounded by fibrous, non-contracting tissue. The portal ramifications are not interfered with as in the ordinary cirrhotic liver; there is seldom venous obstruction; dropsy is rare. The liver may weigh six or eight pounds, quite double its usual size, and the spleen is more or less enlarged. In Case I splenic engorgement was very noticeable at an early period but was not found after death.

The subjects of this disease may be young, as in the cases reported above, not seemingly broken down by drink; whereas atrophic cirrhosis is a disease of slow production, not very common even in drunkards before the age of fifty years. Ascites then first directs attention to the malady, while in the hypertrophic form jaundice is an early sign, and delirium, convulsions and coma more frequently precede death, which is said to be caused by biliary poisoning.

Without entering too much at length into the histories of these cases, I wished to record them on account of their comparative rarity, which may be inferred from the fact that, with the exception of a case reported by Dr. Doe several years ago, no other similar cases have been verified at the City Hospital, I think, although the same symptoms have been noticed in one or two other patients who went away.

— An exchange speaks of a young physician, who has just established himself, and has very little practice, but who is noted for his braggadocio. One of the older physicians, meeting him on the street yesterday, asked him how he was coming on. "I've got more than I can attend to," was the boastful reply. "I had to get out of my bed five times last night." "Why don't you buy some insect powder?" asked the old doctor.

C. M. GREEN, M.D., SECRETARY.

MAY 8, 1886, the President, DR. A. D. SINCLAIR in the chair.

DR. F. MINOT reported a case of

EXTENSIVE PHLEBITIS AND PELVIC ABSCESS FOLLOWING ABORTION.[1]

DR. STRONG gave the following account of the patient before she entered the hospital:

The patient was between two and three months pregnant, and succeeded in the induction of abortion by the use of gin and ergot. The entire ovum came away; but the patient, supposing an afterbirth should also come away, made several attempts to remove what she supposed was the placenta, but what proved to be the posterior lip of the cervix: this she succeeded in nearly pulling off. At the end of a week the patient was doing well; but a few days later there was an attack of uterine pain and fever: phlegmasia came on, and the case was sent to the hospital. No abscess was recognized, although carefully looked for.

DR. MINOT, in reply to questions, said that the most noticeable features in the case, when the patient first entered hospital, were phlegmasia and a slough on the calf of the leg and heel. It seemed remarkable to him that there was so little pain or tenderness in the abdomen. In regard to the use of antipyrine, he thought it gave comfort to the patient in many different classes of cases. He regulated the dose according to the temperature, giving 20 to 30 grains when the temperature was high. He had found the drug of great value in the hectic fever of consumptives: in such cases he gave smaller doses, because the temperature was not high; perhaps eight grains in the afternoon, about an hour before the time of febrile exacerbation. He had never seen any depression following the use of the drug, although it sometimes caused sweating and vomiting.

DR. LYMAN thought it strange that in so large a proportion of cases the phlebitis occurred on the left side. He believed in the use of small doses of antipyrine, enough to bring the temperature down to what might be called the temperature of the disease, and not to the normal point: he thought the exhibition of large doses was followed by too much depression.

DR. E. M. BUCKINGHAM reported, by invitation, the following case of

POSSIBLE AIR-EMBOLISM AFTER LABOR, WITH RECOVERY.

A lady of twenty-seven was delivered of her first child by forceps, after a tedious labor, and with the following circumstances:

The pains had been inefficient, and excepting that for a short time the anterior lip had been a source of annoyance by falling over the head, inefficiency of pains had seemed to be the only reason for the slowness of the labor.

She was etherized for operation and during etherization she vomited, but the mouth was wiped out and there was no choking, for which reasons, as well as for another which will appear later, it is perhaps fair to

[1] See page 279.

conclude that no obstruction was caused by vomited matter lodging in the air passages. Etherization was not very profound, not enough so, indeed, as was shown by a pain occurring as the head passed the perineum. Forceps were applied with the patient on her back across the bed, her legs being steadied by the nurse and the husband. Extraction of the child's body was hurried because the cord was wound tightly about its neck and was pulseless, and I was unable to loosen it. The uterus followed the child down. Unfortunately, the perineum was torn and it was sewn up with three sutures, as soon as the placenta had been removed. After this ergot was given and the patient was then placed in the ordinary position in bed. There had been no particular loss of blood, and the uterus did not dilate unless while I was at work on the perineum.

Almost immediately on changing position she began coughing continuously and with great violence, the face became livid, the pulse weak with 150 beats to the minute, the respiration rapid and laborious, and she cried out that she was faint, and asked if she were dying. Air could be heard entering both lungs. The heart sounds were weak but no murmur nor other abnormal sound was heard, although as no stethoscope was used and the patient was violently shaken by the cough, it is possible that such may have existed. Any attempt at altering her position from the back increased her distress, especially an attempt to turn her toward her left side. She was given fresh air, together with small, frequently repeated quantities of brandy and of coffee, and in all twenty drops of laudanum in divided doses. In two hours after the occurrence of these alarming symptoms she was coughing much less and said that she was somewhat easier. She was, however, still livid. The pulse was weak, but had fallen to 120, and the respirations were 60. Brandy and coffee were continued, with hot milk. Two hours later yet, Dr. Swan saw her with me. The number of respirations had sunk from 44 to 48 in the minute and the pulse was stronger. The second sound of the heart was weak even compared with the first. The abdomen was somewhat tympanitic and therefore the binder which had been applied was loosened. It was agreed to give digitalis, if the heart should fail. In the evening, some twelve hours after labor, color was improving, but no further change had occurred in pulse or respiration. Carefully moving the patient across the bed increased her distress.

On the following morning, February 15th, the pulse was 110, a gain of ten beats; respiration 36, a gain of eight to twelve breaths. She was now able to lie on the right side, but was not allowed to try the left. Tincture of digitalis was prescribed, ten drops every eight hours, in order to lessen the need for brandy, of which more than half a pint had been used. By the third morning the second sound of the heart was louder and had resumed its normal relation to the first sound, the number of pulse beats and respirations remaining, however, about the same. By the fourth morning the pulse was less than 100, and on the fifth day the number of respirations sank to 20. On the sixth day the patient was allowed to lie on the left side while I was present and suffered no inconvenience, she having then a pulse of 96, respiration 22.

The case went on improving steadily; but not until the fourteenth day was she allowed to sit up, although it caused no inconvenience at that time; she then had a pulse of 78 and respiration 16.

Dr. Minot had seen one quite similar case: it did not occur to him at the time that it was a case of air-embolism; but possibly it was.

Dr. J. S. Greene, present by invitation, said that some years ago he had studied the subject of air-embolism, and had made notes from time to time of reported cases. By his own reading and by the experiments of others, he was led to believe that there is a great variety of symptoms of air-embolism. Experiments have been made in which large quantities of air had been injected into the veins of animals; but there is no experiment to prove what symptoms may follow the introduction of small quantities of air clinically. The subject needs further study and elucidation: careful records should, therefore, be kept of all cases. When supposed air-bubbles are found in the veins *postmortem*, they should be examined chemically: such bubbles may sometimes prove to be not air, but the product of decomposition. It did not seem to him that Dr. Buckingham's case was one of air-embolism.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.[1]

SCARLET-FEVER AND SCARLATINIFORM ERUPTIONS FOLLOWING INJURIES AND OPERATIONS,

by Dr. I. E. Atkinson, of Baltimore.

The speaker first referred to the literature of the subject referring to the cases on record. In many of these cases, it was held that the affection had been a true scarlatina. In other cases the scarlatiniform rash was of a septic origin. Various drugs which are frequently prescribed in traumatic cases will produce such eruptions, special reference being made to the cinchona alkaloids. The eruptions produced by these drugs are usually of an urticarial appearance, but they may be of scarlatiniform nature. The following conclusions were presented.

(1) Unprotected persons who have suffered injury or undergone operation are much more liable to scarlet fever than healthy individuals. This probably holds good with reference to other infectious diseases.

(2) When an epidemic tendency to these symptoms prevails after injuries and operations, it may be concluded that true scarlet fever is present.

(3) Septicæmia is occasionally accompanied with a scarlatiniform eruption.

(4) Medicinal eruptions, especially from cinchona alkaloids, may follow accidents and injuries.

DISCUSSION.

Dr. P. A. Morrow, of New York. The speaker has not mentioned the rash which often follows the use of antipyrine, which frequently simulates scarlatina although it is usually of a more measly character. Again, carbolic acid and iodoform dressings will often produce rashes presenting the objective appearances of scarlet fever. There is another eruption known as the "doctor's rash," which appears upon the persons of sensitive individuals stripped for examination. I have seen this in several cases, in one of which it was very marked.

Dr. L. N. Denslow, of St. Paul. I recall the case of a young woman who stated that a scarlatinous eruption always appeared upon her body on exposure

[1] Concluded from page 262.

to sunlight. In order to test the matter, she was directed to come to the hospital closely veiled and gloved. She was then placed in a dark room and one glove removed. A ray of sun-light was then allowed to fall upon the hand and at once a strip of erythema appeared. The same occurred on the face when it was exposed.

DR. I. E. ATKINSON, of Baltimore. While I have seen the rash mentioned by Dr. Morrow, I did not consider them in my paper because I was specially interested in these scarlatiniform eruptions following traumatism and referred to medicinal eruptions only incidentally.

FRIDAY. — THIRD DAY.

MORNING SESSION.

DR. J. E. GRAHAM, of Toronto, Canada, exhibited the specimens from a case of ainhum.

The first paper was entitled

REMARKS AND QUERIES ON, AND AS TO THE RELATIVE FREQUENCY OF MOLES AND THEIR PATHOLOGICAL CHANGES ON THE HEAD AND FACE,

by DR. S. SHERWELL, of Brooklyn.

The history and etiology of this class of affections is very slightly referred to in works on dermatology, but the author's experience has led him to pay increased attention to these formations. In looking up the statistics of one of the institutions with which he is connected, he found that in a period of eighteen months he had seen forty-seven cases suffering with neoplastic and hypertrophic growths. In thirty-six of the cases the growths occupied the face and head. In only eleven cases were the growths found on the body and limbs. Seventeen of the cases in which the growths were on the face were classed as epithelioma. It might be urged that the exposure of the unclothed portions of the body would lead to the formation of neoplasms, and the occurrence of destructive activity in them. If that were so, why should not telangiectasic deformities, nævi, etc., undergo degeneration? The speaker had never seen malignant action, or what simulated it in such growths. Mechanical irritation of the parts might be considered one reason for the frequency of these growths and their malignant tissue alterations, but other parts of the body would seem more exposed to irritation than is the face. Moles and similar growths, while common on other parts of the body, as well as on the face, yet in other situations they seem less likely to undergo destructive pathological changes. The field electively most inimical to the presence of these growths and destructive activity in them, when already present, may be bounded thus: a quadrangle, just taking in the lower lip, the corners of the mouth, extending back to the ears on both sides, vertical lines extending upwards to about an inch above the supra-orbital ridge, united by another horizontal line. Of the space thus included, the vicinity of the eyelids and bridge of the nose was, in the author's experience, the most usual seat of these growths.

The most rational explanation for the frequency of these growths in the situations described is the nature and abundance of the circulatory nutrition, which must favor hyperplasia. If, however, we accept the above hypothesis, why should these errors of the capillary system, such as nævi, not oftener degenerate? He had frequently operated on these latter deformities, often causing much irritation, but has never seen more than a slight keloid change result. The speaker then referred to the special danger of malignant degeneration which attended the presence of moles in persons of advanced life.

In regard to treatment, he stated that he had operated on these growths in many ways, and had come to the conclusion that when malignant action is either present or suspected, the combination of Volkman's curette, followed by the potential cautery, is the most efficient and easiest method of treatment. Of all escharotics, he preferred the liquor hydrargyri nitratis.

DISCUSSION.

DR. I. E. ATKINSON, of Baltimore. The probable explanation of the frequency of moles, etc., upon the face, as compared with other portions of the body, is that, when in this situation patients seek relief, while when covered with clothing attention is not attracted to them. We should expect that sebaceous new growths would be more commonly seen upon the face, because there we have the greatest activity of the sebaceous apparatus.

DR. JAMES C. WHITE, of Boston. I think with Dr. Atkinson, that these new formations referred to are not more frequent on the face than on other portions of the body. That they undergo degeneration and form epitheliomatous new formation on the face more frequently than on other parts of the body, I think cannot be doubted. In regard to the possibility of angiomatous formations undergoing degenerative processes, I have never seen them undergo the so-called malignant change, but they do undergo degenerative processes tending to a spontaneous cure.

I formerly used the liquor hydrargyri nitratis to a large extent, but within recent years I have used the concentrated nitric acid, and seem to obtain about the same effect.

DR. E. B. BRONSON, of New York. I think that in the cases of syphilitic growths, the mercurial preparation is more active than the pure nitric acid, and tends to promote more rapid absorption.

DR. L. N. DENSLOW, of St. Paul. With reference to the caustic, I may say that for the past year I have used a solution of one drachm of bichloride of mercury in one ounce of traumatacine. Its application is not painful at first, and does not excite inflammation for some time. It is particularly useful in the case of children.

DR. R. W. TAYLOR, of New York. The author is to be congratulated upon the clear manner in which he has called attention to the danger of these various growths upon the face in a person over forty-five years of age. Such growths are very prone to assume malignant action. In the same connection, it may be remarked that any inflammatory mass about the prepuce, particularly if the result of anterior lesion, should, in old persons, always be ablated.

NOTES OF A CASE OF EXFOLIATIVE DERMATITIS (PITYRIASIS RUBRA (?)), WITH BULLOUS LESIONS,

by DR. W. A. HARDAWAY, of St. Louis.

February 21, 1886, the author was called to see Mrs. X., with an annoying disease of the skin. The patient was forty-five years of age, stout, and somewhat nervous. She had always been healthy. The present disease came on February 1st, after a night of fatigue and exposure to the night air. The following day a red patch appeared on the pit of the

stomach. Others developed, soon running together, leaving no healthy skin between. There was very little scaling at first, and no moisture. There was some degree of pruritus. When seen by the author, the chest, arms, back, and thighs presented the usual appearances of pityriasis rubra. There was neither moisture, crusts, nor appreciable infiltration. The skin was shining, and of a violaceous hue. In the morning a handful of scales could be gathered from the sheet, but they were not as large as is usual, and were inclined to be furfuraceous. The face was not involved. Three or four days after the first visit, there appeared upon the thighs, abdomen, and buttocks, a number of tense bullæ. Their appearance was preceded by a distinct chill, and followed by a moderate elevation of temperature. The blisters did not run into each other. The bullæ appeared in successive crops of not more than a dozen, each crop being preceded by a chill. Quinine was freely administered, and at the end of a week the bullæ ceased to appear. Dr. Hardaway was obliged to discontinue his visits at this period of the case, but the patient gradually improved.

The writer thought that this and other cases which he had seen showed that diseases usually supposed to run a dry course may, under certain circumstances, be complicated with lesions containing fluid.

A CASE OF PROBABLE TUBERCULOSIS OF THE SKIN,

by DR. G. H. TILDEN, of Boston, Mass.

The patient, a healthy-looking boy of two years of age was first seen in July, 1885. The only lesions were six or eight cutaneous lesions scattered over various parts of the body. These were about the size of a split-pea, slightly elevated above the level of the skin of a bright red color, which disappeared entirely on pressure. These nodules were hard to the touch, with borders of sensible infiltration. These lesions had appeared within the previous five months and had been very slow in growth. During the previous three months there had been failure in appetite and strength and the child exhibited an indisposition to walk. He was under observation for three months during which time one or two fresh nodules appeared. In nearly all of the older ones, there ensued softening with formation of pus which discharged and was followed by cicatrization. About two weeks after the first visit a fluctuating swelling of the size of a hen's egg made its appearance on the inner side of the left thigh over the knee-joint, but not communicating with it. This was opened and pus discharged. It healed in a week. The general health became visibly affected. In November there appeared in the left buttock a swelling which gave an obscure sense of fluctuation. In the proximal phalanx of one finger there appeared a pyriform enlargement resembling that seen in dactylitis syphilitica. The child was again seen in February. The swelling in the buttock had increased in size and there was more fluctuation in it. There was at this time, sufficient outward curvature of the lumbar vertebræ to justify a diagnosis of Pott's disease. In his remarks with reference to the case, the speaker said that in the outset the diagnosis of the nature of the cutaneous lesion had been impossible, but from the subsequent course of the disease he thought the most probable diagnosis to be tuberculosis of an unusual form. In arriving at a conclusion, the following affections were considered: furunculus, erythema nodosum, sarcoma, and syphilis.

DR. LE GRAND N. DENSLOW, of St. Paul, made a supplementary report with reference to

THE TREATMENT OF ACNE BY THE USE OF SOUNDS.

At the last meeting he had reported five cases in which this plan of treatment had been of value. Four of these cases were adults, and all had remained well. The fifth case was that of a boy about fourteen years of age, and in this case relapse had occurred.

DR. S. SHERWELL, of Brooklyn. I have treated cases of acne with the use of sounds and I believe that it does good. I employ this method as an adjunct to other treatment. I of course do not use it in all cases.

A communication with reference to the organization of a Congress of American Physicians and Surgeons was received and the following committee of conference, to report at the next annual meeting of the Association, was appointed: Drs. H. G. Piffard, of New York; F. B. Greenough, of Boston; R. B. Morison, of Baltimore; G. H. Tilden, of Boston, and LeGrand N. Denslow, of St. Paul.

The following officers were elected:

President, Dr. H. G. Piffard, of New York.

Vice-Presidents, Dr. F. B. Greenough, of Boston; Dr. R. B. Morison, of Baltimore.

Secretary, Dr. G. H. Tilden, of Boston.

Treasurer, Dr. LeGrand N. Denslow, of St. Paul.

The Association then adjourned to meet at the call of the Council.

Recent Literature.

A Manual of Surgery. In Treatises by various authors. In three volumes. Edited by FREDERICK TREVIS, F.R.C.S., Surgeon to, and Lecturer on Anatomy at the London Hospital. Vol. I. General surgical affections; the bloodvessels, the nerves, the skin. Vol. II. The thorax, the organs of digestion, the genito-urinary organs. Vol. III. The organs of locomotion and of special sense; the respiratory passages, the head, the spine. Duodecimos. 1866 pp. 213 engravings. Per volume, cloth, $2.00. Philadelphia: Lea Brothers & Co. 1886.

The work appearing under the above title is the production of thirty-three writers, including the editor, many of whom are recognized authorities in their especial subjects.

It is published in the compact, neat form which characterizes the manuals of this series, each volume containing about six hundred pages, systematically arranged and conveniently indexed. Also in each is a list of contributors, table of contents, and separate index of subjects, to which is added, in Volume III, a general subject index of the whole work.

Each article is headed with the name of its author, and heavy-type headings render easily intelligible to the reader its plan of subdivision and classification. The work aims to be an epitome of the leading facts and principles of modern surgery included under the clinical history of surgical affections, their diagnosis and treatment.

Brevity is everywhere a striking feature of the work. Theories are conspicuous by their absence, and only those (as a rule) which have stood the test of experi-

ence are even alluded to, except to be declared worthless. Pathology is introduced only so far as it directly affects the clinical history and intelligent treatment of the affection described.

The general principles of operative surgery are concisely stated, but the technical details of special operations, except such as are atypical, for example, gastrotomy, nephrectomy, *et alii* are intentionally omitted. This is somewhat disappointing, since more attention to this department would have added much to the value of the work. A knowledge of the best methods for typical operations is far more frequently required than of those strictly atypical, especially in a manual designed for the use of students or practitioners — to be used by the former to prepare for general surgical practice, and by the latter as a book for rapid reference when in doubt as to the special operative treatment in any particular case.

In regard to atypical operations also, a more detailed description would, in some instances, add greatly to the value of the article; for example, the description of intestinal resection; no mention is made of the form of needle best fitted for suturing the intestine.

In some instances, an operation is alluded to without any attempt to describe it; for example, thyroidectomy. The different articles are, however, all well written, some exceedingly so, and any omission is perhaps due to the limited space allotted the author. The contents of the different volumes is stated by the above titles, and the few criticisms to be made are chiefly regarding minor details, which will probably be altered in a subsequent edition.

The article on tumors would be greatly increased in value by the addition of illustrations, for in no department of medicine is their assistance better appreciated than in that of pathological histology, and the excellent figures and diagrams in other parts of the work make their absence here the more conspicuous.

In the article entitled "General Principles of Operative Surgery" — an interesting and valuable one — it is to be regretted that this very important subject is so concisely handled. Apparently the great influence in operative surgery of certain pathological conditions, for example, chronic parenchymatous nephritis, entitles them to a much less abridged notice.

Volume III is especially well written, and contains, in an epitomized form, the latest views, both clinical and operative, in those branches of surgery, in which within a comparatively brief period such rapid important changes have occurred. The intestinal suture described on page 266 of this volume is usually credited to Gussenbauer, not Gegenbauer.

The articles throughout the entire work contain data of value, especially to a practitioner who has not time to read an extensive monograph, while some of the subjects are written in a manner which makes them almost ideal articles of reference.

The editor and his colleagues are to be congratulated on the successful result of their efforts, and the work they have produced justly deserves the high commendations with which it has been received.

— The number of students in the Imperial University at Tokio is said, by the *Medical Record*, to be nearly one thousand, a large proportion of whom are students of medicine. Five of the professors in the medical faculty are Germans.

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 23, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

RECENT VIEWS ON "RAILWAY SPINE."

A BRIEF report upon Duménil and Petel's investigations on spinal concussion was given last year [1] in the JOURNAL, but since then the subject has been discussed at considerable length, and the theory that the symptoms observed in such cases are simply manifestations of a traumatic hysteria has been vigorously attacked. Thomsen and Oppenheim, in a discussion of anæsthesia in general,[2] before Duménil's paper appeared, assert that hysterical anæsthesia is so capricious in its onset, its oscillations, and its disappearance, that a stationary condition of the disturbances of cutaneous and special sensibility, lasting for a long time, is extremely rare. After speaking of several diseases where anæsthesia is a symptom, they report a number of cases of injury to the head and of "concussion;" and, after quoting the well-known conclusions of Walton and Putnam, they assert, basing their statements on their own cases, that the discovery of anæsthesia or hemianæsthesia, with an implication of the special senses, does not suffice for a diagnosis of hysteria, since this symptom may be found in other functional and organic diseases of the central nervous system. In these cases the course is stable, and exhibits none of the changes characteristic of hysteria, especially the sudden improvements; the prognosis for recovery, too, is unfavorable. The mental condition is not like that of hysteria, but there is often a constant condition of melancholia. Besides that, there are sometimes symptoms pointing to severe and irreparable disease of the nervous system — Argyll-Robertson pupils, optic atrophy, genuine epilepsy, vesical paralysis, and progressive paralysis of the extremities. A part of the symptoms may be functional, but the whole disease is not necessarily functional, and functional and hysteria are not synonymous terms.

Page, in a fresh consideration of the subject,[3] considers the trouble a mixed one. There is first a sprain,

[1] Vol. CXIII, p. 296.

[2] H. Thomsen and H. Oppenheim. Ueber das Verkommen und die Bedeutung der sensorischen Anästhesie bei Erkrankungen des centralen Nervensystems. Archiv. für Psychiatrie, xv., 2, 3, pp. 559, 633, 1884.

[3] H. W. Page. On the Abuse of Bromide of Potassium in the Treatment of Traumatic Neurasthenia. Medical Times and Gazette, April 4, 1885.

which, by causing pain and stiffness in the back, may direct attention to the spine. In addition to that, the accident produces a severe mental effect, so that, even without any injury, there may be collapse. This is followed by headache, pains, weakness, prostration, and fatigue on exertion. The patient becomes nervous, weak, emotional, melancholy. There is a lowered nerve force, neurasthenia. This may be attended with functional "hysterical" disorders, anæsthesia, paralysis, catalepsy, and trance. The neurotic suffer most. All these cases tend to recover, but recovery may not be complete in severe forms, and various causes — melancholia, the prospect of damages, and the improper use of bromide of potassium — may delay it.

Charcot[4] attacks the conclusions of Thomsen and Oppenheim with great earnestness, and defends the theory of the hysterical nature of the affection. He affirms that these grave and obstinate nervous states, rendering work impossible for months or years, are only hysteria, nothing but hysteria. In the female, the symptoms of hysteria are usually unstable, although they may be tenacious, but in the male they are often fixed and tenacious, and resist treatment. Melancholia is not uncommon in the male. This permanence prevents their recognition. Charcot cites cases in "La Salpètrière," among them a case of right hemianæsthesia with a classical limitation of the field of vision, where the symptoms had been observed for twenty years without even a temporary modification. Hystero-epileptic attacks have been observed in some of the traumatic cases, but in others they may fail, and we may find only the permanent stigmata of hysteria, anæsthesia, contractures, etc.

In a recent paper devoted exclusively to this trouble, Oppenheim reports ten new cases and defends his former position.[5] It is difficult to say how far the mental shock plays a part in the ætiology, but all the patients exhibited some mental alteration, melancholia, emotional disturbance, terror or sleeplessness. There was, however, no disturbance of the intelligence. Vertigo and faintness were not uncommon, and one suffered from genuine epileptic attacks, while another had petit mal, and another had attacks of confusion with hallucinations, the psychical equivalent of epilepsy. Headache, pressure in the head, vertigo, tinnitus, and loss of sexual power were also observed. There was usually anæsthesia, including anæsthesia of the special senses, but true hemianæsthesia was rare; if one-half of the body was markedly affected, however, the other half was found to be less sensitive than normal. Bilateral symmetrical anæsthesia was also seen. Limitation of the visual field may or may not be present. In many cases the mobility of the legs was impaired, and the patients were very cautious about jarring the vertebral column. The gait was slow and straddling, and they sometimes staggered with the eyes shut. Tremor and hemiparesis were also noted. Some patients had much difficulty in micturition, one having to use the catheter; others suffered from constipation. Two patients had some optic atrophy, a third Argyll-Robertson pupils with inequality. These symptoms Oppenheim claims differ from those in the cases reported by Charcot, and he asserts that Charcot is enlarging the already vague boundaries of hysteria by admitting permanent states of depression among its symptoms. Autopsies are lacking; but in two of his cases a portion of the nervous system, the optic nerve, showed visible morbid changes. If this is a symptom of hysteria, he says, then the firmest pillars of our knowledge are overturned. Although epilepsy in various forms was seen, hystero-epilepsy with its grand movements, *arc du cercle*, was absent. He repeats his former statement that anæsthesia with implication of the functions of special sense is not characteristic of hysteria. Other symptoms observed, too, are not common in hysteria: obstinate headache, vertigo, vomiting, motor disturbances, loss of virility, disturbances in micturition, and the girdle-feeling, beside Argyll-Robertson pupils and optic atrophy. He concludes that the symptoms developing after railway injuries, etc., do not present a single uniform type, that in many cases they do not agree with any one form of disease, that some cases are a mixed form of psychosis and neurosis, while a large percentage indicate definitely a lingering organic disease of the nervous system. He reasserts, too, that a functional nervous disease is not necessarily hysteria. The prognosis, of course, is often very important. He differs from Page, who thinks that most cases finally recover, and states that he has never seen perfect recovery.

Westphal, who some years ago advanced the hypothesis of little foci of myelitis or encephalitis, or foci of multiple sclerosis as a cause for these troubles, has recently stated[6] that he sees no reason for bringing such cases under the rubric of hysteria.

Not even Oppenheim would venture to deny that grand hysteria or neurasthenia may be caused by injury, especially by such injuries as railway accidents. The cases reported by Charcot, Page, Putnam and Walton seem to have established this fact beyond question. It is a different matter, however, when the claim is made that the majority of cases of "railway spine" are hysteria. It would be difficult to make the cases reported by Oppenheim fit any definition of hysteria as we ordinarily recognize it, and, in fact, the evidence of organic change in the nervous system in some of his cases seems conclusive. We shall probably have to admit that several different affections, some functional and some organic, may result from railway injuries, although at present our knowledge is too uncertain to make a correct classification. Above all, autopsies, with a careful examination of the nervous system, are essential.

THE INDEX-CATALOGUE. VOLUME SEVEN.

THE seventh volume of the Index-Catalogue of the Library of the Surgeon-General's office, completes the index through Leghorn and thereby gives the student of medical literature control over certain very important subjects: the intestines, the jaw, the joints, the kidneys, the knee-joint, labor, the larynx, etc. The Index with its present issue comprises 70,500 book titles and 254,000 journal articles. There is prefixed to this seventh volume a consolidated list of all the abbreviations used in the first seven volumes of the catalogue, which has been prepared to obviate the necessity of consulting in some cases, several volumes in order to determine the precise scope of a given abbreviation. It would almost seem as though the fact that this volume contained such a list might properly have been noted on the cover. "The additions to the abbreviations of titles published in each volume have become so numerous as to make a consolidation necessary for the convenience of the reader," but only those on intimate terms with the great index will know of the existence of this perfected list, or be able to remember the volume which contains it. It is, however, pretty certain that a supplemental list will again be necessary before the Index is completed. There will be required six or seven more volumes which will at the present rate require as many years for publication. During that time there are sure to appear a certain number of new periodicals, undoubtedly their number could be pretty accurately foretold by comparison with the past, and the new publications must be represented by their appropriate abbreviations.

A very little use of the Index makes evident the very great care that has been bestowed upon it, in order that it may reach the highest possible degree of usefulness. The long lists of titles under important heads are carefully subdivided so that one is able to refer at once to the minute portion of the great subject in which he is interested. In the present volume, for instance, *Intestines* is divided into many subheads, *Abnormities and malformations of; Absorbtion by; Adhesions of; Animals, insects, etc., in;* and so on, the larger subheads being divided again and again, as *Intestine, (obstruction of); treatment of by abdominal section; by electricity;* and so forth.

One sometimes hears a regret expressed that our republican government cannot, or does not, give to scientific medicine the same encouragement that is afforded by some of the more autocratic governments of the old world, by the maintenance of professorships whose incumbents devote their lives to scientific research. It is a gratification to know that in a different way our own government is exerting an influence in raising the average of medical knowledge. The manner in which this is being effected by the government was very forcibly brought out by Dr. Billings in his recent address before the British Medical Association, and patriotic physicians may find cause to temper their regrets with the reflection that our government in its own way is doing an important work for the profession.

After speaking of the Army Medical Museum, Dr. Billings says of the library:

"The library, which commenced in a collection of those books relating solely or especially to military medicine or surgery, which were required in the compilation of the 'Medical and Surgical History of the War' has expanded into a great medical library which is one of the best practical working collections of the kind in the world. These collections then no longer appertain exclusively or chiefly to the business of one department, but belong to the whole profession of the United States as a body; and the department which has charge of them is managing them from this point of view. The influence of the library in stimulating research and upon the quality of medical literature is already very perceptible and is destined to increase with advancing years. I think I may also venture to claim that the utility of these collections and especially of the library is by no means confined to the medical profession of the United States, for the catalogues and indexes which are being issued in connection with them, are of service to medical writers and teachers all over the world."

This is by no means overestimating the valuable influence of the Surgeon-General's library, and of its index-catalogues. The latter has been a stimulus to other medical libraries in the preparation of their own particular catalogues, and has helped to keep alive that enthusiasm which makes the collection and preservation of books a pleasure and not a labor. The library of the Boston Medical Library Association is particularly rich in medical journals and its librarian has from the first taken pride in seeing its sets of valuable journals complete. It is hardly possible to estimate the value which has been added to the collection by the index to periodical literature which the index catalogue contains.

It is now comparatively easy to know all that has been written on any given subject, or rather all that is contained in the Surgeon-General's library which is about as near all as one library can ever contain, and of course the work of a man who desires to look up the literature of any given subject is comparatively lightened.

MEDICAL NOTES.

— The death of Dr. James G. Wakley, for twenty-five years editor of the *London Lancet*, occurred August 30th, from cancer of the tongue. He was the youngest son of Thomas Wakley, founder of the *Lancet*. Dr. James Wakley succeeded his father, on the latter's death in 1862, as editor of the paper. An older brother was associated with him as half-proprietor of that journal.

— Herr Paul v. Ritter, of Basle, has signified his intention of leaving 300,000 marks to the University of Jena, for the purpose of promoting the study of

philogenetic zoology according to the Darwinian theory. He will give 130,000 marks at once, and the balance will be paid after his death. Professor Haeckel, of Jena, an enthusiastic teacher of evolution, proposes to use the gift for the establishment of a professorship of zoology to be called, after the donor, the Paul v. Ritter Chair of Zoology.

— A serious and remarkable case of poisoning is reported in the British medical papers as having occurred at a wedding breakfast in Carlisle. In all, nineteen persons, partook of the meal. Four only escaped unharmed. One person, the bride herself, died on the fifth day. The dishes were all prepared by a professional cook the previous day, and kept in a dry, cold cellar. No peculiarity of taste was noticed, except a little bitterness of some of the jelly. The symptoms were much like those of cholera. They were peculiar in appearing late. The breakfast was at noon; some of the persons were taken ill at 8 P.M., others at midnight, some the following day, and one on the second day. The source of the poisoning is as yet wholly unknown. Metallic poisons seem to have been excluded, and some ptomaine has been suspected.

— In the discussion at the recent meeting of the British Medical Association at Brighton, on the duration of life with heart-disease, Dr. Bristowe made some very excellent and apposite observations on this subject. "It is," he said, "quite early enough, in my opinion, for a man to know that he has heart-disease when he begins to feel the effects of it;" and with this sententious remark most practitioners will agree. Incalculable harm has often been done by the abrupt announcement that a patient has cancer, or that another has heart-disease; and the evil is aggravated by the fact that, as in all other human affairs, the diagnosis may be wrong, or the prognosis may not be realized. Sir Andrew Clark told a very amusing but instructive anecdote of his having been called to see a gentleman suffering from bronchitis, who, fifty years before, had been precipitately superanuated on full salary, an the announcement by the medical officer to an insurance-company that he was the victim of an incurable form of heart-disease, and would probably not live more than six months.

— Toronto does not seem to be an encouraging place in which to practise medicine, according to the following paragraph, which has been going the rounds of the medical press, under quotation from the *Toronto Globe*: "There is only one medical man in this city who last year earned $5,000 from his profession, combined with the interest he received on his previous savings. There is not one man on the list who had $4,000, and only four who touched $3,000. When we come to the comparatively modest and moderate $2,000, we naturally conclude that we shall have a full legion. But no, we have only fourteen, all told, who came up to this figure. When we come to between $2,000 and $1,000, the number becomes encouragingly large. As many as fifty-one of the best-known and greatly-sought-after doctors of our city are put down under their own hands and seals as having last year lived on from $1,000 to $1,800. Some of these are professors. There remain only the unfortunates who worry along from $800 down almost to zero. Of these, we are sorry to say, there were last year thirty-six." How the exact figures were ascertained it does not appear, but we trust the amounts returned are not (as in some cases is to be suspected) an exaggeration over the reality. An accurate statement of professional incomes for any given locality, which are very difficult to obtain, would be of a good deal of interest to the resident profession.

NEW YORK.

— The Board of Health has decided to employ twelve physicians in vaccinating service for the next two months.

— The State Board of Health suffers a severe loss in the resignation of Dr. E. M. Moore, of Rochester, which has just been announced. Dr. Moore was one of its original members and has always been one of the valuable and active workers in its service.

— Dr. William W. Jackson, for the past ten years physician to the City Prison and medical examiner of the Department of Charities and Correction, died September 15th, at the age of fifty-six years. He had had a very large experience as an expert in insanity, and was highly esteemed both for his skill and many amiable qualities.

— Mr. Parrott, a reputable engineer, has undertaken to criticize the building of the proposed great Quaker Bridge dam for the formation of a storage reservoir, on the grounds both of inadequacy of supply and unhealthfulness. Notwithstanding the enormous proportions contemplated for it, he claims that it will not be sufficiently large to hold the surplus water of a wet year in a dry one. As to the question of unhealthfulness, he estimates that the artificial lake thus created will receive the entire drainage of about one-half the total area of three increasingly populous counties. This lake, according to his calculations, will have a border of seventy-eight miles' length, with flat and miry shores; so that when the water is level with the aqueduct opening there will be nearly 3,000 acres of "malarial mud" exposed to the summer sun, while the residue which the aqueduct cannot empty will constitute a pool of eight billion gallons stagnant from year to year. Whether Mr. Parrott's views are correct or not, the matter would seem to be worth thoroughly investigating before the building of the big dam is commenced.

The plan which he proposes in place of the one now contemplated, is to abandon the near-at-hand water-supply, and derive the supply from Ulster and Greene counties on the west shore of the Hudson where he finds an ideal drainage and storage territory. This will long be sparsely inhabited, and there are numbers of spots where brooks may be dammed within deep and rocky reservoirs; offering a strong contrast to the flat basin within the Quaker Bridge dam. The

various reservoirs could be connected by tunnels, and all, he thinks, could be drained into Esopus Creek, from whence the main supply could start for the city through a pipe line from an elevation of five hundred feet above tide level.

Miscellany.

FAREWELL DINNER TO DR. R. T. EDES.

A FAREWELL dinner was given to Dr. R. T. Edes at Young's Hotel, Boston, Friday evening, September 17th, prior to his departure for Washington where he intends to make his home and practise his profession.

About thirty of Dr. Edes's medical colleagues sat down at the table with him, the staff of the City Hospital, the Harvard Medical School and the Dorchester Medical Club being especially represented. Dr. Francis Minot presided, and addressed the guest of the evening on behalf of the Harvard Medical School; Dr. H. W. Williams spoke for the staff of the City Hospital; Dr. W. S. Everett for the Dorchester Medical Club, and short speeches were also made by Drs. Wigglesworth, Morton Prince, W. L, Richardson and George B. Shattuck. Sincere regret at Dr. Edes departure from Boston, and warm wishes for his future welfare and happiness were the common sentiments expressed by all. It is not given to every one to resign a hospital appointment and a Harvard professorship in the prime of life and excite thereby the real regret of younger as well as of older colleagues. The evening closed with the singing of "Auld Lang Syne," and was as enjoyable as the occasion for the gathering would allow it to be.

DILATATION OF THE STOMACH IN CHILDREN.

IN the *Archives of Pediatrics* for July, 1886, there is a review of an article on this subject by Blache from the *Rév. Mens. des Mal. de l'Enfance*, February, 1886. According to this author the condition is not a rare one among children, especially as the result of continued digestive troubles where there is alternation of diarrhœa and constipation. A number of such cases have been seen by the author in children between the ages of twelve and eighteen months, especially among those who have been fed from the bottle and have been fed too frequently. Less frequently the same condition occurs among children who have been nursed at the breast. In most of the author's cases there was a precedent condition of gastro-enteritis. Moncorvo, of Rio Janeiro, who has also written upon this subject, found that most of his cases originated from bad hygienic surroundings, from hereditary syphilis, or from malarial intoxication; but this experience did not occur to the author, the digestive and intestinal troubles, as already observed, being most prominent as causative influences. The stools in these cases are frequent, watery, and contain, more or less, half-digested food with an abundance of epithelium from the intestinal mucous membrane. They are discharged from the bowel in a stream or jet, and are accompanied by the passage of gas. They sometimes have a fetid odor and sometimes an acid one, or no odor at all. Their greenish color is a noticeable point, the color being due to a change from the natural brown or yellow by the action of the acid juices which convert a portion of the bile into biliverdine. They also contain a quantity of glairy mucus. All these indications point to an advanced condition of gastro-intestinal catarrh, and in nine times out of ten the author affirms that a dilated condition of the stomach will coexist. Thus, it is seen that a dilated condition of the stomach is only an attendant phenomenon of a local or diathetic diseased condition. The diagnosis of this condition is not thought to be a difficult matter, even though the præ-gastric walls do not project beyond the general level of the surface of the body. By placing the child upon the back and drawing up the knees a sound may be obtained by percussion, which is called a hydro-aërial sound, which indicates a dilated condition of the stomach. Of the consequences of this condition two at least are to be noted, one having reference to the heart and lungs, the other to the nervous system. As to the former, the author has noticed that in some children the excessive enlargement of the stomach is associated with dyspnœa and with cardiac palpitations; as to the latter, night-terrors have sometimes been associated. In addition to the excessive and improper feeding which may produce this condition the author also mentions as exciting causes, weaning, dentition, and bad hygienic surroundings. A tonic and reparative treatment is, of course indicated.

REFLEX NERVOUS PHENOMENA FROM INJURIES TO THE TESTICLE.

WE note the two following cases illustrating serious reflex symptoms following wounds of the testicle and the tunica vaginalis. The first occurred during the tapping of a hydrocele, and is described in the *Lancet*, July, 1886, p. 23. M. Loumeau tapped a hydrocele in a healthy man, aged forty-four, and drew off about one hundred and twenty-five grammes of clear fluid. The operator then injected gently sixty grammes of a mixture of tincture of iodine with twice its volume of water. All at once the patient complained of severe pain in the spermatic cord and loins, with cramp in the right forearm. The ulnar border of the right hand then became flexed, the ring and small fingers being completely bent, while the index and middle fingers became flexed at their metacarpo-phalangeal articulations. The thumb also was flexed and brought near the fingers. Exactly the same position was shortly afterwards assumed by the left hand. There were no convulsions nor syncope. After a few minutes the ulnar muscles began to relax, and the index and middle fingers became flexed completely on the hand, which itself became strongly flexed on the forearm. All the muscles on the front of the forearm became hard and contracted. The palmar fascia was strongly retracted, and the palmaris brevis quite tense. On both sides the ulnar affection had given place to contraction of the muscles supplied by the median nerve. The tongue hung loosely in the mouth, and the patient was unable to articulate a sound. The forearms were shampooed, and nearly an hour afterwards the muscles relaxed. The patient recovered completely, leaving the hospital cured, in a few days. The author had no idea of the cause of this attack, but attributed it to reflex irritation of the nerves of the serous membrane of the testicle.

The second case is one of sudden death from a blow on the testicles, and is reported in the *London Medical Record* (August 16) from the Bulgarian *Meditzinsko Spisanïë*, June 20, 1886. A man, aged between forty-five and fifty, fought with a woman on the street. During the fight the woman dealt a violent blow on his genital organs. The man shouted, "I am dying," staggered, and fell insensible. The author, Dr. Ivanoff, who was almost immediately fetched to the spot by a policeman, found the patient lying on his back, motionless, pulseless, and breathless, his face, neck, and scrotum being very red. Not a trace of ecchymosis or any other signs of injury was detected anywhere in the man. Since there seemed to be heard a slight cardiac murmur, and a slight tremor to be felt in the carotides, Dr. Ivanoff, without any delay, resorted to artificial respiration. But neither forty-five minutes' manipulations nor electrization could establish the man's breathing. The congested parts soon became livid, and every sign of life extinct. At the post-mortem examination, there were found only intense congestion of the meninges and brain, congestion of the lungs, with numerous punctiform ecchymoses, accumulation of dark-red fluid blood in the cardiac cavities, congestion of the stomach, liver, kidneys, and testicles. Everything else was quite normal. Basing his conclusions on all the facts, as sketched above, Dr. Ivanoff stated (forensically) that death followed from syncope, which had been brought about by sudden violent pain caused by a blow on the testicles.

REPORTED MORTALITY FOR THE WEEK ENDING SEPTEMBER 11, 1886.

Deaths reported 1,896: under five years of age 909: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 517, consumption 215, lung diseases 78, diarrhœal diseases 283, diphtheria and croup 80, typhoid fever 45, malarial fever 32, whooping-cough 25, scarlet fever 16, cerebro-spinal meningitis seven, measles six, erysipelas three. From malarial fevers, New Orleans 11, St. Louis six, Baltimore five, Brooklyn four, Charleston three, Philadelphia two, District of Columbia one. From whooping-cough, Brooklyn nine, Pittsburgh six, Baltimore and District of Columbia four each, Lowell and Cambridge one each. From scarlet fever, St. Louis four, Brooklyn three, Baltimore. Cincinnati and Pittsburgh two each, Philadelphia, Fall River and Lynn one each. From cerebro-spinal meningitis, District of Columbia four, Fall River, Gloucester and Fitchburg one each. From measles, Brooklyn and Pittsburgh two each, Philadelphia and Salem one each. From erysipelas, St. Louis two, Brooklyn one.

In the 22 cities and greater towns of Massachusetts, with a population of 1,015,634 (population of the State 1,941,465), the total death-rate for the week was 23.61 against 20.51 and 22.88 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending August 28th the death-rate was 20.1. Deaths reported 3,497: infants under one year of age 1 233; acute diseases of the respiratory organs (London) 160, measles 57, scarlet fever 49, whooping-cough 48, fever 35, diphtheria 27, diarrhœa 562.

The death-rates ranged from 13.9 in Bristol to 26.8 in Preston; Birmingham 21.0; Blackburn 19 1; Hull 17.4; Leeds 21.2; Leicester 24.7; Liverpool 24.6; London 18.3; Manchester 23.7; Sheffield 22.0; Sunderland 18.4.

In Edinburgh 16.6; Glasgow 18.7; Dublin 18.2.

For the week ending August 28th, in the Swiss towns, there were 30 deaths from consumption, diarrhœal diseases 17, lung diseases 13, diptheria and croup one, whooping-cough seven.

The death-rates were: at Geneva 9.1; Zurich 11.5; Basle 19.2; Berne 21.4.

The meteorological record for week ending September 11, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, Sept. 11, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 4, 1886, TO SEPTEMBER 17, 1886.

MIDDLETON, P., major and surgeon. Assigned to duty at St. Francis Barracks, St. Augustine, Fla., as post-surgeon. S. O. 126, Division of the Atlantic, September 2, 1886.

LA GARDE, L. A., captain and assistant surgeon. Upon departure of 3d Infantry from Fort Ellis, M. T., to proceed to Camp Sheridan, Mammoth Hot Springs, Wyo. Ter., and report to the commanding officer for duty, relieving Assistant Surgeon Pilcher. S. O. 87, Department of Dakota, August 27, 1886.

WAKEMAN, WM. J., first lieutenant and assistant surgeon. Granted leave of absence for one month, with permission to apply for three month's extension, to take effect when his services can be spared in the Department of the Platte. S. O. 207, A. G. O., September 6, 1886.

PILCHER, JAMES E., first lieutenant and assistant surgeon. When relieved by Assistant Surgeon La Garde from duty at Camp Sheridan, to return to his proper station, Fort Custer, M. T. S. O. 87, Department of Dakota, August 27, 1886.

WALES, PHILIP G., first lieutenant and assistant surgeon. Granted leave of absence for one month with permission to apply for an extension to November 5, 1886. S. O. 70, Division of the Pacific, August 31, 1886.

BANISTER, WM. B., first lieutenant and assistant surgeon, (recently appointed). To report by letter to the commanding general, Department of Arizona, for assignment to duty. S. O. 208, A. G. O., September 7, 1886.

WALKER, F. V., first lieutenant and assistant surgeon. Assigned to temporary duty at Fort Adams, R.I. S. O. 131, Division of the Atlantic, September 8, 1886.

WALES, PHILIP G., first lieutenant and assistant surgeon. Resignation accepted by the President, to take effect November 5, 1886. S. O. 212, A. G. O., September 11, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING SEPTEMBER 18, 1886.

SIMONS, M. H., passed assistant surgeon. Detached from the "Alert," and placed on waiting orders.

NORFLEET, E., passed assistant surgeon. Detached from the "Alert" and placed on waiting orders.

BOGERT, E. S., medical inspector. Ordered to Navy Yard, New York, September 28, 1886.

RESOLUTIONS IN MEMORY OF CHARLES D. HOMANS, M.D.

The Surgeons of the Massachusetts Charitable Eye and Ear Infirmary have heard with profound sorrow of the death of Dr. Charles D. Homans, the President of the Board of Trustees of the Infirmary.

They wish publicly to express their high esteem for his character and their sense of the void his death leaves, both in the profession and in the community.

They recall with pleasure his genial and manly presence, his skill as a physician, his manner courteous and kindly to all, his years of gratuitous service in the relief of the sick and suffering, and with deep feeling regret that a life which promised years of continued usefulness should now be brought to a close, and they would herewith tender to the family and friends a sincere and heartful sympathy in their affliction.

(Signed.)

BERIBERI IN BRAZIL.

BY HORACE M. LANE, M.D., OF SAO PAULO, BRAZIL.

Having occasion to visit all of the principal cities of Brazil twice during the past year, I embraced the opportunity to collect such facts as were accessible concerning this strange disease, which, of late, seems to have embraced the whole Atlantic coast of Brazil from 5° north of the equator to 28° south. We have no assurance that it may not yet invade our Gulf coast, where there is a considerable strip of country within the limits ascribed to it, and where conditions apparently favorable to its development exist.

I was shown every courtesy by resident physicians of public or private hospitals, and officials in charge of penal institutions. It was, however, extremely difficult to get statistics of mortality of beriberi, or the extent to which it prevailed; the epidemic was always just in advance, and I never came up with it. There exists a great deal of confusion in the minds of many physicians as to exactly what constitutes a case of beriberi, but in some places, as was observed in the early days of the disease in India, there is a tendency to call every fatal disease of debility or obscure case of dropsy or paralysis, beriberi, so that it is impossible to reconcile statements made concerning it at different points on the coast. I have, therefore, shaken together the results of all of the observations made in upwards of one hundred cases, at Para, Maranham, Pernambuco, Bahia, and Rio de Janeiro, and endeavored to give a fair general view.

It is by no means as new in South America as is generally supposed. The first recorded observation of the disease is found in an old Portuguese work of 1756 (1),[1] where it is described as seen in Maranham, in the first half of the last century. Nothing is heard of it for one hundred years or more, when it is again recognized in Bahia (1860). It is probable, however, that it existed in Maranham and the neighborhood from the time of its first settlement, unrecognized, and treated as rheumatism, scurvy, or some of the ordinary medullary and cardio-hepatic diseases. It is also certain that it existed in Bahia many years before the epidemic of 1863 (2). At this time, however, it attracted the attention of observing physicians of the place, among whom were Drs. Patterson, Wurcheron, and Silva Lima, the latter writing and publishing, in 1872 (3), an elaborate description of its clinical features, based upon one hundred and twelve cases, and a review of the literature of the subject, making it clear that the disease was the veritable beriberi of India. It is to be regretted that this eminent clinician has not revised his work of fifteen years ago, and given to the profession the results of his later observations and riper experience, and of the extensive pathological research he is known to have made during this time. With his unrivalled opportunities and his acknowledged ability, no one could make a more valuable contribution to the literature of this obscure subject.

The geographical limits of the disease are now enlarged to include various points of India, the Malabar coast, part of Ceylon, Java, a limited area in Africa, China, and the coast of Bengal, Borneo, Cuba, Paraguay, and Brazil. It has a remarkable tendency to select certain strips of coast, leaving others in the same latitude, and apparently in the same condition untouched. Thus it is found in Java, while at Baly (Clapham), separated only by a narrow strait, it is unknown. In Cuba it has never been recognized out of Cardenas. It occupies the whole coast north of Madras (Lat. 13° 6′ N.), but is never seen south of it (Aitken). It is found only on the west side of the Bay of Bengal, from 15° to 20° N. Lat. In India it never extends more than forty (4) to sixty miles from the coast (Morehead), while in South America it has been seen in Matto Grosso (Araujo Braga), five hundred miles from the coast, and fifteen hundred miles up the Amazon (Herndon), and in São Paulo, at an elevation of nearly three thousand feet (Bertoldi), and in Bolivia, on the Atlantic slope of the Andes. It has been seen as far north as 40° Lat., and as far south as the 28th parallel, though it may be said to be limited to about 25° either side of the Equator. It is a singular fact that the disease has not yet been found in the West Indies, except at Cardenas, in Cuba, nor on the west coast of Africa, nor north coast of South America, nor in any part of Central America or Mexico, or the United States (5).

The very name is suggestive of something foreign, and we are prepared to learn that it is of Indian origin. Its etymology is obscure. It is probably from the Singhalese word *beri*, meaning weakness, inability — equivalent to our generic term *disease*. The repetition is common in the East to indicate intensity. It has also been said to come from the Hindoostanee word *bheri*, a sheep, from the resemblance of the doubling gait of the beriberic patient to the walk of a sheep. Others trace it to bhebheri, meaning numbness, rheumatism, a sore or swelling.

The word was found in use on the Malabar coast, where the disease was first discovered, and has been handed down by Anglo-Indian and Dutch medical writers, as a name for almost every fatal disease of debility, such as various kinds of paralysis, reflex paraphlegia, dropsy, anasarca, scurvy, anæmic rheumatism, various heart diseases, etc., known in the East. Later writers, however, have used it with greater precision. It is known in Japan as kake-kake (6); in Ceylon, as the bad-disease. The "Parangi" — which depopulated the "Vanni" district in Ceylon, and reduced it to a jungle, was probably *beriberi* (Evezard and Clapham). In Africa, it is the *sleeping sickness*. Authors speak of it as *Hydrops Asthmaticus, Indosynclonus, Synclonus-Beriberia*, etc., etc. So much for the name.

The disease, as found on the Brazilian coast, may be defined as "a constitutional disease, characterized by dropsy, paralysis, degeneration of muscular tissue, and progressive anæmia, whose chief features are numbness of surface, and hyperæsthesia of deep muscles of the extremities — gradual and incomplete ascending paralysis, both motor and sensory. Total absence of fever. Præcordial oppression, scanty and high-colored urine, hoarseness, and dusky discoloration of the skin, the fatal cases terminating by suffocation, asphyxia, or asthenia; favorable cases by an abundant flow of urine (Silva Lima), slow convalescence, and great tendency to relapse (Lacerda)."

Clinically, it may be divided into three forms: 1. The *paralytic*, dry, or atrophic form — *B. Atrophia* — where paralysis is the marked feature, and where there is a deficiency of fluids in the vessels, with, in rare cases, muscular atrophy. 2 The *œdematous* or wet

[1] These figures refer to the Bibliography at the close of the article.

form — *B. Hydrops* — in which there is a watery condition of the blood, with effusions into the cellular tissue and serous cavities. 3. The *mixed* — *B. Polysarcia* — where symptoms of either or both the other forms are found, with wide variations, and where the sharp lines of difference are lost.

There are two well-marked stages: the prodromic and the active. There is, in the first, a tired feeling, indisposition to move, weakness about the legs; in walking, a slight inclination of the toes to drag, obliging the patient to step higher than usual, inability to retain on the foot the heelless slipper usually worn by the poorer classes of Brazil; a drowsy feeling, and a sense of extreme shortness of breath on the slightest exertion, loss of appetite, and a sense of fullness at pit of the stomach; slight pains, generally attributed to rheumatism or neuralgia; numbness and tingling at tips of fingers, and of toes, around corners of mouth, and over anterior tibial muscles, a sensation around the waist as of a cord drawn tightly, with a knot over the epigastrium, and a slight pain at or beneath lower end of sternum. Up to this point, the symptoms are common to all forms of the disease. In the *paralytic* form, the patient now begins to feel anxious, the skin of the legs becomes dry and falls *asleep;* there is great sensitiveness, on pressure, about the deeper muscles of the calves of the legs, the belt gets tighter, and the knot over the epigastrium larger and harder, and distresses the patient fearfully, the tightness sometimes reaching up to the axilla, the dyspnœa becomes frightful, the face assumes a livid hue, the pulse becomes small and weak, the urine scanty and almost the color of coffee, the appetite lost; sometimes there are partial convulsions, clonic spasm of the muscles; patient complains that he is suffocating, is covered with cold, clammy sweat, and does really die of suffocation, in full possession of his mental powers, and *without* fever.

In the second form, the dyspnœa is a troublesome symptom and very early there is an unaccountable sense of weariness (canceira); there is an apparent swelling and hardening of the calves of the legs, which is, however, only a contraction of the surrounding tissue; the tendon reflexes are usually exaggerated, rheumatic pains in, and heaviness of the feet, the anasarca, a pathognomonic symptom of this form, first appears in the anterior part of the leg, and *not in the feet*, as in other diseases. The pulse is full and compressible, a systolic murmur is heard over the pulmonary valves, and in the large arteries; the patients become low spirited and alarmed. The dense, and slightly elastic œdema increases everywhere, hardly pitting at all on pressure. The serous cavities fill with effused liquid. There is a slight degree of numbness and often a little paralysis; the urine is, as in the first form, scanty and high-colored, of acid reaction and spec. grav. 1007-1030. Death comes by asphyxia, visceral congestion, or occasionally, by embolism of pulmonary artery (Silva Lima), and sometimes suddenly and unexpectedly (Lacerda).

The symptoms of the third form vary greatly. Sometimes the paralytic, and sometimes the œdematous predominating, and sometimes both come on simultaneously. These are the cases that become suddenly bad, and are known as "*Gallopante*" galloping, or acute pernicious form, the patient dying in six to twenty-four hours. In the mixed form, the sensitiveness of the muscles is very great, the feeling of exhaustion very pronounced; the dyspnœa great, swiftly progressing to asphyxia; there is a rapidly ascending paralysis, involving all of the respiratory muscles. The paralysis, either motor or sensory, is never complete. The sphincters are never involved in either form. There is never œdema without some paralysis, nor a case of pure paralysis, without some œdema; the diaphragmatic belt, a characteristic feature of the disease, is always present, but much more marked in the paralytic than the wet form. Rapidly increasing œdema marks the gravity of the case. In all cases there is a peculiar pufliness and lividity of the face, sometimes producing a mottled appearance. The white line produced by drawing the finger across the surface disappears slowly. In the œdematous cases there is an extreme turgidity of superficial vessels, and not infrequently pulsation of the jugulars. There is often tenderness of the periosteum of the long bones, with a peculiar roughness of surface. Digestion is nearly always deranged; dysentery, diarrhœa, and other tropical diseases often complicate it. Urine is *always* scanty, high-colored and contains epithelial cells, and degenerate fat corpuscles, with urate of ammonia, but rarely any albumen. It is to be regretted that no accurate quantitative analysis has been recorded that shows the amount of urea secreted. The skin is dry and harsh. The walk of the beriberic is unique, resembling that of a child learning to walk; the forward movement is nearly normal, the trouble being in recovering the feet. There is also a peculiar hoarseness of the voice in this disease, accompanied by a jerky, sighing breathing. Many of the isolated symptoms might be attributed to other well-known diseases; it is the grouping together, the peculiar association of the separate features that marks this formidable disease as *sui generis*.

In a disease characterized by symptoms so constant and marked, we should naturally expect to find marked anatomical changes, but we are disappointed. There are no constant lesions met with either in the cord, or large organs that cannot be considered secondary; the blood alone shows important morbid changes in the destruction and degeneration of the red disks, and has evidently lost its nutritive and oxygenating properties. The areola tissues of the heart, lungs, brains, and abdominal viscera, are found soaked in serous fluid, with effusion into the cavities; in eighty per cent. of the wet cases the pericardium is found distended with fluid, containing flakes of fibrin. In this variety the heart is found enlarged, softened and flabby, of pale-yellow color, filled with dark blood, sometimes fluid, sometimes clotted; when the latter, the dark clot extending into the pulmonary artery and large venous trunks. The muscular tissue of the heart-walls is always found undergoing fatty degeneration (which according to Ondenhover, is often the cause of death). The same condition is found in the tissue of the paralyzed voluntary muscles. In the paralytic form the heart is smaller and empty, and the degenerative changes are less marked.

The appearance of the brain and cord is variable: sometimes the medullary substance seems harder than normal, oftener, however, it is softened. It is frequently found, with ecchymotic spots at emergence of the nerves, the meninges are injected; the cord is sometimes altered by minute effusions of fluid into its substance, congestion of its vessels, spots on the surface of the arachnoid; microscopic examinations have

revealed annular sclerosis invading the antero-lateral pillars, with encysted granular masses in different parts of the spinal marrow. Sclerotic patches in the lumbar and dorsal regions of the cord are often found, the nerve tissue is often yellowish white and granular in appearance (Lacerda). Proliferation of interstitial connective tissue in the lateral columns and posterior roots is found. These varying conditions of the cord, however, do not always bear a just relation to its known mechanism in producing the symptoms found. Serous effusion into the minute connective tissue is the only constant change found.

There is evidently, first, a paresis of the cardiac ganglia, rendering the heart weak, and emptying its cavities; rapid degenerative changes follow in the muscular walls; there is a feeble vis-a-tergo and they yield to blood pressure, thereby producing dilatation and tricuspid insufficiency, with the inevitable regurgitation, capillary stasis and dropsy. A vaso-motor paralysis, acting in like manner upon the pulmonary arteries and arterioles, accounts for the murmur. Congestion alone may destroy life by impairing functions,— by sheer physical changes, and the inevitable consequence which want of circulation entails upon the blood;— blood-stasis, and separation of the elements, formation of coagulum, deposit of pigmentary matter, faulty oxygenation, etc.

If we allow ourselves to consider a single symptom or group of symptoms, the diagnosis is somewhat puzzling; but if regarded as a whole, the symptoms and physical signs present a case not easily mistaken. The individual symptoms, or even a group of the symptoms, may be found in rheumatism, myelitis, trichinosis, scurvy, reflex paraplegia, ordinary anasarca, pernicious anemia, and often the bronzed skin of Addison's disease is observed, granular degeneration of the kidneys, the cachetic dropsy of Andral, various forms of heart disease, and almost every disease due to profound anemia; but in all these there is some essential feature lacking, or in beriberi, there are well-marked symptoms incompatible with the known facts in other diseases. It is essentially a disease of inanition; there is starvation of the cerebro-spinal centres, and consequent anemia, from some important change in the blood that impairs the complex process of nutrition.

The pathognomonic features are the gait, fatigue, the diaphragmatic belt, and incomplete ascending paralysis, never involving the sphincters. The anæmia can hardly be said to be a distinguishing feature, as it is the most common of all conditions incident to tropical life.

What can we say of the cause of the disease? We cannot resort to that convenient term, malaria or marshmiasm,—the great asylum of all obscure diseases,—as it has none of the chief characteristics of malaria, no chill no fever, and when epidemic, almost no recoveries. It has a much narrower limit, also, and is not found in many places where malarial disease most abounds. Then, again, when we say malaria, we say nothing precise or definite, and before we use the term in so important a connection, we should at least define it, and give its elements a fixed character, and explain their *modus agendi*. We have only two points to guide us: first, its limited range and erratic distribution; second, the fact that it requires a residence of six or eight months to be subject to it.

One is thoroughly impressed with the belief that it depends upon some specific poison generated outside of the body; this belief finds corroboration in the fact that Dr. J. B. Lacerda, Director of the Government Laboratory of Experimental Physiology in Rio, and the discoverer of the application of permanganate of potash to snake-bites, has actually found in the spinal marrow and blood of persons dying of beriberi, and isolated, a germ which is in some manner constantly related to the disease.

Dr. Lacerda (7) has published a very interesting work, describing the micro-germ, and telling how he discovered it. He also finds the identical germ in certain kinds of rice. This receives strong support from observers in India where rice is one of the articles of diet *prohibited* to beri-beric patients. This talented observer has, during the past year, pushed his studies into a still more interesting field, and has found the microbe of beriberi to be identical with that which produces the horse-pest (*Peste de Cadeiras*) in the great island of Marajo (8). This disease of horses, in its clinical features, so closely resembles beriberi in the human subject, that Dr. Lacerda's discovery causes no surprise. It also receives strong support from the fact that, wherever the pest exists there also beriberi is found; to wit: in Bolivia, on the Solimoes (Herndon) Mattogrosso, Madras, (9) etc.

The limits of this paper oblige me to forego the pleasure of giving a synopsis of this most interesting work of one of Brazil's foremost investigators. Suffice it to say, that he follows Pasteur's methods, and has isolated this germ, which belongs to the great group of *ascomycites*, and cultivated it, and demonstrated its effects upon various animals, and its causal relation to beriberi, in a most convincing manner. If we accept this, the pathology is comparatively simple. The wide diversity of symptoms is explained by the periods of vegetation, or greater or less activity of the germ, as well as the varying susceptibility of persons attacked. The universal law governing the action of these micro-germs also obtains; in order that they may become noxious elements it is necessary that the normal forces of resistance be lowered, or that some inter-current abnormal condition be present, lack of acclimation is simply lack of habit to resist.

The question naturally suggested is, does the poison primarily affect the blood or the nervous system? The first evidence of morbid change is in the nervous system. The pain, an early and a characteristic symptom, depends upon a hyperæmic condition of the affected parts, due to a vaso-motor paralysis. The varying periods of incubation do not imply any difference in the character of the germ, but it is a question of the quantity introduced and the degree of resistance which it meets. The evidence that there is a primary lesion in the cord is strong; the paralysis is due to pressure from effusion; the effusion dependent upon rapid, destructive changes in the blood. The distrophy, the marasmus, would be indirectly connected with the disturbed function of the cord. The œdema would be referred to the disturbance of the vaso-motor enervation.

The slight paralytic disturbance, in the wet form, where trophic changes predominate, only shows how variable is the localization of the medullary trouble, now in the motor region, and again in the trophic area. Admitting the existence of a specific germ, we easily understand how the pathological changes are most sharply accentuated in the spinal marrow; a se-

lective affinity, which is a property of all morbigenic germs, enables it to seek the spinal marrow, as the most congenial breeding ground.

Once established in the cord, it has a two-fold action, a mechanical and obvious one, blocking up the capillaries, and disturbing the interstitial circulation, producing congestion, compression of the cellular elements, and consequent atrophy; a chemical action produced by the poisonous detritus, or ptomaines of the micro-organism, in its rapid reproductions, with their well-known fermenting and dissolvent action upon the blood, which is the receptacle of all the residue of organic cellular life; and this explains the dyscrasia, and the rapid and general serous transudation, the acute anasarca, which is the gravest feature of the disease. Now, then, it is not difficult to connect the symptoms with the lesions of the cord, as far as observed, and which are located chiefly in the lumbar and dorsal regions. When we remember that the spinal cord more completely fills the vertebral canal in the dorsal region, than either above or below, it will be understood how symptoms from serous effusion and other lesions will manifest themselves, first, by paralysis and unsteadiness of the lower limbs. Again, the nerves which supply the skin and muscles of the leg and foot arise from the third sacral, and are damaged by a lesion involving the lower part of the lumbar enlargement. It will be remembered that one of the earliest symptoms is a pain in the lumbar region. The actual loss of sensation with wasting points, especially if irregularly distributed, as in beriberi, refers to damage of the nerve-roots, outside of the cord, and relates to the meninges rather than the cord. This, too, coincides with observed lesions. (Lacerda.) Subacute and symmetrical myelitis of the anterior cornua, in the lumbar and cervical enlargement, causes paralysis and atrophy of all four extremities, the upper part of the limbs being normal; the sclerotic patches already mentioned, and other changes are most frequently found in this region.

The morbid agent and its products are eliminated slowly through the kidneys.

It is generally supposed that the number of deaths from beriberi is greater than that of any other disease on the Brazilian coast. I am inclined to think that this is an exaggeration. The percentage of deaths among those attacked is very much smaller than it was fifteen years ago, and it would be safe to say does not exceed 30 to 40 per cent.

Dr. Silva Lima's report of 112 cases gives the death-rate as 62.50 per cent. as follows:

Paralytic, 66 cases with 33 deaths . . 50 %
Œdematous, 23 cases with 18 deaths . 78.26 % } 62.50%.
Mixed, 23 cases with 19 deaths . . . 82.60 %

In India the death-rate is usually about 25 to 30 per cent. (Malcolmson).

The coast line where it prevails in Brazil, is nearly 5,000 miles long, from Manáo's, on the Amazon, to Santa Catherina, and its existence at all seasons of the year enables the aggregate of its victims to reach a high figure (10).

Concerning the treatment: this is extremely simple. Drugs do no good whatever. The patient should be removed at the earliest possible moment to a place where beriberi does not prevail. Bahia, beautifully situated along a high ridge, easily drained and continually exposed to the sea breeze, seems to be the headquarters of the disease. If patients are removed early before irreparable damage has been done, to the island of Itaparica, a low, flat place, just across the bay, they recover almost as if by magic.

The treatment should plainly be directed to removing the effused fluids, regulating the functions of the important abdominal viscera, especially the kidneys, increasing the action of skin and restoring to the blood its normal constituents; to these ends diuretics, cathartics and tonics are indicated. In India, Maxwell gave phosphorus in substance in 1–2–3 grain doses with success (11). (Lacerda explains the predilection of the micro-germ for the nervous tissue by the fact that this tissue abounds in phosphorus and he observed that the microptyte multiplied most rapidly in a culture acidulated with phosphoric acid.) A great variety of medicines are given, but change of surroundings is the only thing that cures, and in the acute pernicious type this fails. In Pernambuco a preparation of the "Mandioca" plant is used, and has a local reputation. It is simply a powerful diuretic. The *treek-farook*, so extensively used in India, is composed chiefly of terbinthinates with rhei and acts as a prompt diuretic and cathartic (12).

REPORT ON THERAPEUTICS.[1]

BY FRANCIS H. WILLIAMS, M.D.

ERGOT.

NOT long ago, Professor Kobert showed that the noteworthy constituents of ergot are ergotinic acid, which does not promote uterine contractions, and cornutine and sphacelinic acid, which do. What he has published in the *Practitioner*[2] will be found of interest.

"Ergotinic acid: As regards this substance and its sodium salt, I may say I have administered it internally and hypodermically to pregnant bitches, rabbits, cats, and sheep. The doses given were at first small, and then increased, till finally they were toxic. The results of all these experiments entirely agreed with my former ones; when administered internally, even the largest doses are well borne, without the supervention of uterine contractions, and without any material disturbance of the mother. At most, the stools became semi-fluid. When injected subcutaneously, relatively large doses cause complete narcosis, lasting twenty-four to forty-eight hours, during which reflex action ceases; nevertheless, neither contraction of the uterus nor expulsion of the young occurs.

"After very large doses the blood-pressure falls very low, and, as a consequence, the young die, but are not expelled. From these experiments, it will be

[1] Concluded from page 279.
[2] Vol. 35, p. 415.

seen that ergot of rye does not owe its ecbolic power to the ergotinic acid contained in it, and that we may consider as clinically worthless all preparations of ergotinic acid, and of sclerotinic acid (so-called) and all aqueous extracts which do not contain those principles which are soluble in alcohol.

"Cornutine: This substance is now prepared and supplied commercially by Gehe & Co., and is not to be confounded with the very different ergotinine of Tanret. The latter is quite inert. The former, however, produces uterine contractions, both in animals which are pregnant, and those which are not pregnant, but with the difference that in these latter the contractions are accompanied by coincident vomiting, diarrhœa, salivation, and irregularity of the pulse; but in the former, the irritability of the uterus is much increased, and, as a consequence, the uterine movements come on after doses so small that no other symptoms at all appear. Consequently, it was always possible, in dogs and cats, to bring about the expulsion of the fœtus without seriously jeopardizing the life of the mother, when the cornutine was injected subcutaneously. It was a matter of no consequence whether the young were mature or not. The amount necessary to accomplish this result was less than an eighth of a grain. Gehe's preparation, not being as yet a chemically pure one, must be administered in larger doses.

"Sphacelinic acid: This is a resinous body, insoluble in water, and consequently, must be administered by mouth in the form of an emulsion. In dogs and cats, a sufficient dose never failed to evoke powerful labor pains in the pregnant uterus, followed rapidly by the birth of the fœtus; yet not one of the mother animals lost her life in consequence. The contractions after this substance we may describe as being tonic, and after the cornutine as being clonic. From the foregoing, it will be seen that in the ecbolic action caused by ergot, both cornutine and sphacelinic acid take part.

"As hinted at in my previous communication to this Journal, cornutine acts by influencing directly the centre for the uterine contractions situated in the spinal cord, but sphacelinic acid acts directly upon the uterus itself. And the combined action of these two substances is necessary if we wish to produce the action of ergot upon the uterus, and yet avoid any other untoward effects. Therefore, the only rational preparation for use in cases of parturition is one which contains all the cornutine and sphacelinic acid, but no ergotinic acid, for the latter is very injurious to the stomach, and has no influence upon the uterus.

"At my desire, Gehe & Co. have been good enough to prepare and supply commercially an article answering the above indications (extractum secalis cornuti cornutino-sphacelinicum Kobert). This is, of course, not in any way identical with other ergotins now in the market. Internally administered, it was, *when fresh*, exceedingly active, producing abortion with absolute certainty in pregnant animals. In the form of pills, it has been employed with success in man to stop hæmorrhages in various organs, and also in the treatment of vascular dilatation in cutaneous diseases. Unfortunately, it does not keep well for more than six months, and must each year be prepared afresh; a preparation a year old is almost absolutely worthless. It is necessary to state that neither ergot itself nor any of the numerous commercial and European and American preparations which I have examined have retained their therapeutic powers for more than twelve months. Of course the ergotinic acid remains unaffected, but this is valueless."

The work of Professor Kobert is valuable and interesting, and, it is to be hoped, will be supplemented by careful clinical observations.

CALOMEL AS A DIURETIC.[3]

Dr. Ernst Jendrássik, assistant to Professor Wagner, of Budapest, has created a genuine surprise by his exposition of a virtue residing in calomel, which has hitherto remained wholly unknown.[4] In fact, though some older writers recommend calomel in dropsy, and also allude to a certain diuretic action of the drug, this property is not even mentioned by any of the text-books at present in use. Wherever calomel is now being used in the treatment of dropsy, its drastic action alone is taken into consideration.

Being called upon some two years before to treat a case of dropsy in view of the wholly obscure causation of the affection and the strong suspicion of a syphilitic basis, our author instituted a mercurial treatment, beginning with inunctions of blue ointment, soon followed by small doses of calomel in combination with jalap. Scarcely two days had elapsed after the calomel treatment when the urine was voided in such quantities that the dropsical infiltration completely disappeared in a few days. A relapse of the dropsy a couple of weeks later was with equal promptness cured by the exhibition of calomel and jalap. This discovery, of course, led Jendrássik to further researches in dropsical cases, in which the diuretic action of the drug was distinctly established.

Calomel was generally given combined with jalap, though this addition is of no importance. Urination increased up to 9,500 c.c., in twenty-four hours, the polyuria usually being proportional to the extent of the œdema present. Jendrássik found that three-grain doses, given three to five times daily, showed the promptest effects. It is important and interesting to note that the diuretic action of calomel only shows itself simultaneously with the appearance of the symptoms which indicate the absorption of the mercury. The diuresis appears three days after having taken the drug and persists until the œdema has completely disappeared.

Constant experiments proved that in the combination doses of calomel and jalap, the diuretic effects referred alone to the first constituent, as the latter never produced these results when given alone.

The degree of the diuresis was found to be dependent upon two factors,— first, upon the size of the dose ordered; and second, upon the extent of the dropsy present. It was observed that the diuretic effects proceeded pari passu with the manifestations of mercurial absorption such as metallic taste in the mouth, increased salivation, stomatitis, etc.

Many of the observations of Jendrássik are too interesting to be wholly omitted.

Employing doses of two to three grains of calomel, he invariably obtained the diuresis, while larger doses, six to seven grains, always failed. Our author justly concludes that in this, as in other instances, the effects of a medication depend not upon the amount of medicine ingested but upon the amount absorbed. In the instance of calomel, larger doses provoke diarrhœa,

[3] Therapeutic Gazette, August 16, 1886.
[4] Deutsches Archiv. für Klinische Medizin, April 22, 1886.

and thus to a large extent prevent the absorption of the drug. But little time appeared to intervene between the taking of calomel and the appearance of its diuretic effects.

If given in the proper dose, the diuresis appeared usually within a couple of days. At the same time it was noted that a certain quantity only of calomel was required to effect the diuresis, and that any further surplus was wholly ineffectual, especially when polyuria had already set in.

The author can give no clue to the manner in which the diuretic action of calomel in dropsy is effected, since neither the heart nor the kidneys are directly influenced.

Experiments made with calomel (and also with jalap) on healthy individuals remained wholly negative; stomatitis and salivation set in, but no polyuria. The same failure was obtained in a case of pleuritic exudation with diminished urination. Still, the hypothesis (as a result of exclusion of other modes) is ventured upon that the primary factor in the diuretic action of calomel is the resorption of the œdematous fluid by the blood.

In high grades of dropsy depending upon heart-disease, the drug evolves its highest diuretic powers; in cases of slight œdema in pleurisy, and in the œdema of kidney-disease, the drug fails.

In conclusion, the undesirable after-effects of calomel, such as diarrhœa and stomatitis, are briefly referred to and means suggested to obviate them. Against the diarrhœa a small dose of opium (one-seventh grain) acts as a sufficient check, without influencing the diuresis.

Stomatitis is to be met by the use of chlorate of potassium given as a gargle, or if this be insufficient, internally (twelve grains daily).

FURTHER OBSERVATIONS ON URETHAN.[5]

Krapelin emphasizes at the very beginning of his paper that the drug produced in no instance any untoward secondary effects, only in the case of an alcoholic subject suffering from gastric catarrh, the stated large quantity of urethan caused vomiting. Interference with the appetite was never observed, even when the drug was given for several weeks in succession. Ten to fifteen minutes after ingestion of the drug a quiet sleep ensues, lasting usually several hours, and from which the patients wake refreshed. If this sleep is interrupted by any external causes, the hypnotic effects assert themselves again after the removal or disappearance of the interference.

Urethan, however, is not an energetic hypnotic and fails usually in cases of intense or even considerable excitation, where it is far inferior to paraldehyde. In delirium tremens especially, Krapelin saw no effects as observed by Sticker. Again, urethan is no anodyne, it does not remove pain, and in this respect can of course never replace morphine. In combination with morphine, urethan seems quite useful.

Krapelin mentions as especial indications for urethan the affections of the melancholic and paralytic type; in mania and as intimated above, in delirium tremens, urethan is useless and paraldehyde ought to be resorted to. Hence we see that only conditions of slight excitation or depression constitute the principal indications for urethan; besides, it is claimed to be useful in exhausting diseases even when fever coexists.

[5] Therapeutic Gazette, August 16, 1886.

The drug has certain advantages over paraldehyde, which cannot be questioned: among these are the longer duration of its effects and the absence of gastric irritation after its use.

Urethan can be taken simply in a watery solution, or, to correct its taste, with tinct. aur. cort.

Hospital Practice and Clinical Memoranda.

CHILDREN'S HOSPITAL.

CASES IN THE SERVICE OF DR. A. T. CABOT.
REPORTED BY MR. W. B. FISKE.

TREPHINING FOR EPILEPSY.—TEMPORARY IMPROVEMENT.

KATE E., six and three-quarters years old, was admitted to the Children's Hospital, May 13th, 1885.

Her parents were healthy and intelligent. There had been no nervous trouble on either side of the family. The child herself was said to have been healthy and perfectly bright until October, 1882. At that time she fell about four feet, making a wound over the left parietal bone.

She was not made unconscious by the fall, but in an hour began to have convulsions which lasted with slight intermissions for twenty-four hours. During the following month they recurred almost daily, gradually increasing in frequency till she once had twenty-three in one day.

When seized with a spasm she would fall down suddenly, grow livid, foam at the mouth, and clench her hands. After a few minutes the muscles would slowly relax and she would pass into a sleep. The body would usually be drawn to the left. About six months after the fall her mental powers began to fail. One year later she was seen by Dr. Cabot, who advised an operation.

At the time of entrance she was an idiot, her mind having failed greatly since she was seen the year before. About one and a half inches above and behind the base of the mastoid process on the left side, could be seen the scar of the old scalp wound. Just in front of this was a slight depression which was almost imperceptible, and could be covered with the ball of the finger. Slight pressure upon this point would make the child dodge the head as though it were painful. The mother said that she frequently put her hand there just before she had a convulsion.

The girl had a clear history of convulsions following an injury. There was a slight depression of the outer table of the skull, and the aura seemed to take its departure from that point. On account of the otherwise hopeless condition, it was decided to trephine, with the hope rather than the expectation of relieving the child by the removal of the depressed fragment, if such should be found. On May 21st, 1885, Dr. Cabot operated with thorough antiseptic precautions.

A crucial incision was made just in front of the scar and over the depression. The whole of the depressed portion was covered by the trephine.

The button of bone removed showed a decided thickening and had a considerable projection from the inner table. There was no intimate adhesion to the dura and no especial thickening of that membrane was noted. A thickened ridge upon the inner table

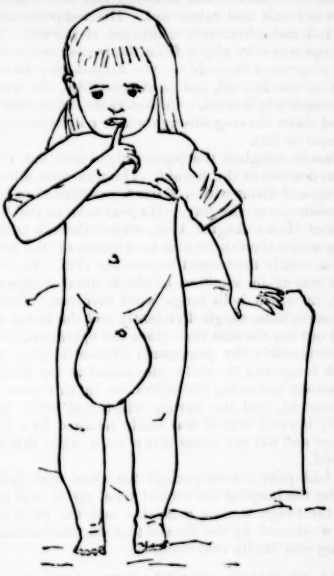
extended from the seat of operation down towards the base of the skull. This, which seemed to be the callus along a line of fracture was cut away with the bone-forceps. A drainage-tube was inserted, the flaps brought together with sutures and the wound dressed with iodoform and Lister gauze. After the operation she was placed in a room by herself, away from the noise of the wards. She was very comfortable until midnight. She then began to have convulsions, and had fourteen in the next eighteen hours. In the first twelve the twitching was noticed to have been on the left side as before the operation, but in the last two it was chiefly on the right. The dressing was changed under the spray, the discharge was very slight and the wound looked well. Ice cap applied. Pot. brom., gr. 10. t. i. d.

She slept well during the night of the 22d, and had on convulsions until the following morning. She had one then and one in the afternoon. They were shorter and less severe than the preceding ones had been and the twitching seemed equal on both sides. She slept considerably during the day but when awake was quite talkative and seemed more rational than she had been. Bromide increased to gr. 50 in the twenty-four hours. The dressing was not disturbed till the 26th, when the tube was removed.

June 1st the wound had healed by first intention and the dressing was left off.

She continued comfortable and seemed to improve in her mental condition. The bromide was reduced and discontinued on June 5th. From May 23d till June 12th there were no convulsions. June 12th she was brought down to the open ward among the other children, and within the first twenty-four hours she had eight convulsions. She remained in the hospital till June 20th, and had convulsions almost daily. From the time of the operation till her discharge, a period of four weeks, she had thirty convulsions. Sixteen of these occurred within two days after the operation, the remaining fourteen in the week after she was brought down among the other children. In the interval of nearly three weeks during which she was isolated she had none.

The mother was advised to take this child to an asylum where she could have absolute quiet, with intelligent watching, in the hope that the conditions which existed for three weeks after the operation might be encouraged and perhaps confirmed. She could not be induced to do so, but took the girl back to her home among other children where the convulsions soon returned and became about as frequent as they had been before the operation.



LARGE SCROTAL HERNIA. OPERATION FOR RADICAL CURE.

The child was two years and a half old. The hernia was first noticed when he was eight months of age. It had increased rapidly in size, so that when admitted to the hospital in June, 1885, the scrotum was as large as a cocoanut, the penis was almost obliterated. The hernia was on the right side. The ring through which it came was very large, easily admitting the thumb. The hernia was readily reducible but all efforts to keep it up by means of a truss had been fruitless. As a large portion of the intestines had been outside of the abdominal cavity for so long a time it was thought best to reduce the hernia and to keep it up, by rest in bed and bandages in order that the abdomen might adapt itself to its increased contents before proceeding to an operation.

This attempt was attended with considerable difficulty; in fact it was found impossible to keep the hernia up by any sort of bandage, as the slightest flexion of the hips would let the bowel out from under the pad. Finally a hip-splint was applied immobilizing that joint, and now pressure could be successfully used and the hernia controlled. It was thus kept in place for a week, and the child then suffering no distension or inconvenience, operation was decided upon.

Dr. Cabot operated July 6th, as follows:—

An incision about two inches long was made over the ring, care being taken not to prolong the incision toward the scrotum any further than was necessary in order to make it possible to keep the dressings from soiling with the urine. The sac was exposed and the

bowel, which was allowed to descend at the beginning of the operation, was reduced to the abdomen. The sac was not opened or ligatured, as a portion of the intestine which seemed like the vermiform appendage, was adherent to it. The ring was represented by a triangular aperture in the abdominal wall with its base about an inch in length upon Poupart's ligament, and with its apex at about the site of the internal ring. The tendinous edges of a considerable part of this opening were so widely separated and so resistant that they could not be brought together. The greatly redundant sac of the hernia was drawn up out of the scrotum, folded together and thrust into the opening. Stitches were then taken through the tissues about the pillars of the ring and these parts were drawn together as far as possible over the plug which the sac made in the ring, so as to hold it in place.

A short drainage-tube was inserted, the wound

closed with sutures and a dressing of iodoform and carbolic gauze applied. In order to keep the parts as quiet as possible a wire hip-splint was adjusted which immobilized the right leg. Every precaution was taken to protect the dressing from urine by means of a rubber cloth.
